EVALUATE: When the slit width *a* is decreased, there are fewer dark fringes. When $a < \lambda$ there are no dark fringes and the central maximum completely fills the screen.

36.4. IDENTIFY and **SET UP:** λ/a is very small, so the approximate expression $y_m = x\dfrac{m\lambda}{a}$ is accurate. The distance between the two dark fringes on either side of the central maximum is $2y_1$.

EXECUTE: $y_1 = \dfrac{\lambda x}{a} = \dfrac{(633\times10^{-9}\text{ m})(3.50\text{ m})}{0.750\times10^{-3}\text{ m}} = 2.95\times10^{-3}\text{ m} = 2.95\text{ mm}.$ $2y_1 = 5.90\text{ mm}.$

EVALUATE: When *a* is decreased, the width $2y_1$ of the central maximum increases.

36.5. IDENTIFY: The minima are located by $\sin\theta = \dfrac{m\lambda}{a}$.

SET UP: $a = 12.0$ cm. $x = 8.00$ m.

EXECUTE: The angle to the first minimum is $\theta = \arcsin\left(\dfrac{\lambda}{a}\right) = \arcsin\left(\dfrac{9.00\text{ cm}}{12.00\text{ cm}}\right) = 48.6°.$

So the distance from the central maximum to the first minimum is just $y_1 = x\tan\theta = (8.00\text{ m})\tan(48.6°) = \pm(9.07\text{ m}).$

EVALUATE: $2\lambda/a$ is greater than 1, so only the $m = 1$ minimum is heard.

36.6. IDENTIFY: The angle that locates the first diffraction minimum on one side of the central maximum is given by $\sin\theta = \dfrac{\lambda}{a}$. The time between crests is the period *T*. $f = \dfrac{1}{T}$ and $\lambda = \dfrac{v}{f}$.

SET UP: The time between crests is the period, so $T = 1.0$ h.

EXECUTE: **(a)** $f = \dfrac{1}{T} = \dfrac{1}{1.0\text{ h}} = 1.0\text{ h}^{-1}$. $\lambda = \dfrac{v}{f} = \dfrac{800\text{ km/h}}{1.0\text{ h}^{-1}} = 800\text{ km}.$

(b) Africa-Antarctica: $\sin\theta = \dfrac{800\text{ km}}{4500\text{ km}}$ and $\theta = 10.2°$.

Australia-Antarctica: $\sin\theta = \dfrac{800\text{ km}}{3700\text{ km}}$ and $\theta = 12.5°$.

EVALUATE: Diffraction effects are observed when the wavelength is about the same order of magnitude as the dimensions of the opening through which the wave passes.

36.7. IDENTIFY: We can model the hole in the concrete barrier as a single slit that will produce a single-slit diffraction pattern of the water waves on the shore.

SET UP: For single-slit diffraction, the angles at which destructive interference occurs are given by $\sin\theta_m = m\lambda/a$, where $m = 1, 2, 3, \ldots$.

EXECUTE: **(a)** The frequency of the water waves is $f = 75.0 \text{ min}^{-1} = 1.25 \text{ s}^{-1} = 1.25 \text{ Hz}$, so their wavelength is $\lambda = v/f = (15.0 \text{ cm/s})/(1.25 \text{ Hz}) = 12.0 \text{ cm}$.

At the first point for which destructive interference occurs, we have $\tan\theta = (0.613 \text{ m})/(3.20 \text{ m}) \Rightarrow \theta = 10.84°$. $a \sin\theta = \lambda$ and $a = \lambda/\sin\theta = (12.0 \text{ cm})/(\sin 10.84°) = 63.8 \text{ cm}$.

(b) Find the angles at which destructive interference occurs.
$\sin\theta_2 = 2\lambda/a = 2(12.0 \text{ cm})/(63.8 \text{ cm}) \rightarrow \theta_2 = \pm 22.1°$.
$\sin\theta_3 = 3\lambda/a = 3(12.0 \text{ cm})/(63.8 \text{ cm}) \rightarrow \theta_3 = \pm 34.3°$.
$\sin\theta_4 = 4\lambda/a = 4(12.0 \text{ cm})/(63.8 \text{ cm}) \rightarrow \theta_4 = \pm 48.8°$.
$\sin\theta_5 = 5\lambda/a = 5(12.0 \text{ cm})/(63.8 \text{ cm}) \rightarrow \theta_5 = \pm 70.1°$.

EVALUATE: These are large angles, so we cannot use the approximation that $\theta_m \approx m\lambda/a$.

36.8. **IDENTIFY:** The angle is small, so $y_m = x\dfrac{m\lambda}{a}$ applies.

SET UP: The width of the central maximum is $2y_1$, so $y_1 = 3.00 \text{ mm}$.

EXECUTE: **(a)** $y_1 = \dfrac{x\lambda}{a} \Rightarrow a = \dfrac{x\lambda}{y_1} = \dfrac{(2.50 \text{ m})(5.00\times10^{-7} \text{ m})}{3.00\times10^{-3} \text{ m}} = 4.17\times10^{-4} \text{ m}$.

(b) $a = \dfrac{x\lambda}{y_1} = \dfrac{(2.50 \text{ m})(5.00\times10^{-5} \text{ m})}{3.00\times10^{-3} \text{ m}} = 4.17\times10^{-2} \text{ m} = 4.2 \text{ cm}$.

(c) $a = \dfrac{x\lambda}{y_1} = \dfrac{(2.50 \text{ m})(5.00\times10^{-10} \text{ m})}{3.00\times10^{-3} \text{ m}} = 4.17\times10^{-7} \text{ m}$.

EVALUATE: The ratio a/λ stays constant, so a is smaller when λ is smaller.

36.9. **IDENTIFY** and **SET UP:** $v = f\lambda$ gives λ. The person hears no sound at angles corresponding to diffraction minima. The diffraction minima are located by $\sin\theta = m\lambda/a$, $m = \pm1, \pm2, \ldots$ Solve for θ.

EXECUTE: $\lambda = v/f = (344 \text{ m/s})/(1250 \text{ Hz}) = 0.2752 \text{ m}$; $a = 1.00 \text{ m}$. $m = \pm1$, $\theta = \pm16.0°$; $m = \pm2$, $\theta = \pm33.4°$; $m = \pm3$, $\theta = \pm55.6°$; no solution for larger m.

EVALUATE: $\lambda/a = 0.28$ so for the large wavelength sound waves diffraction by the doorway is a large effect. Diffraction would not be observable for visible light because its wavelength is much smaller and $\lambda/a \ll 1$.

36.10. **IDENTIFY:** Compare E_y to the expression $E_y = E_{\text{max}}\sin(kx - \omega t)$ and determine k, and from that calculate λ. $f = c/\lambda$. The dark bands are located by $\sin\theta = \dfrac{m\lambda}{a}$.

SET UP: $c = 3.00\times10^8 \text{ m/s}$. The first dark band corresponds to $m = 1$.

EXECUTE: **(a)** $E = E_{\text{max}}\sin(kx - \omega t)$. $k = \dfrac{2\pi}{\lambda} \Rightarrow \lambda = \dfrac{2\pi}{k} = \dfrac{2\pi}{1.40\times10^7 \text{ m}^{-1}} = 4.488\times10^{-7} \text{ m}$.

$f\lambda = c \Rightarrow f = \dfrac{c}{\lambda} = \dfrac{3.0\times10^8 \text{ m/s}}{4.488\times10^{-7} \text{ m}} = 6.68\times10^{14} \text{ Hz}$.

(b) $a\sin\theta = \lambda$. $a = \dfrac{\lambda}{\sin\theta} = \dfrac{4.488\times10^{-7} \text{ m}}{\sin 28.6°} = 9.38\times10^{-7} \text{ m}$.

(c) $a\sin\theta = m\lambda (m = 1, 2, 3, \ldots)$. $\sin\theta_2 = \pm2\dfrac{\lambda}{a} = \pm2\dfrac{4.488\times10^{-7} \text{ m}}{9.38\times10^{-7} \text{ m}}$ so $\theta_2 = \pm73.2°$.

EVALUATE: For $m = 3$, $\dfrac{m\lambda}{a}$ is greater than 1 so only the first and second dark bands appear.

36.11. **IDENTIFY:** Calculate the angular positions of the minima and use $y = x\tan\theta$ to calculate the distance on the screen between them.

(a) SET UP: The central bright fringe is shown in Figure 36.11a.

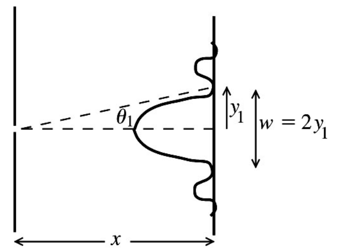

Figure 36.11a

EXECUTE: The first minimum is located by

$$\sin\theta_1 = \frac{\lambda}{a} = \frac{633\times10^{-9}\ \text{m}}{0.350\times10^{-3}\ \text{m}} = 1.809\times10^{-3}.$$

$\theta_1 = 1.809\times10^{-3}$ rad.

$y_1 = x\tan\theta_1 = (3.00\ \text{m})\tan(1.809\times10^{-3}\ \text{rad}) = 5.427\times10^{-3}\ \text{m}.$

$w = 2y_1 = 2(5.427\times10^{-3}\ \text{m}) = 1.09\times10^{-2}\ \text{m} = 10.9\ \text{mm}.$

(b) SET UP: The first bright fringe on one side of the central maximum is shown in Figure 36.11b.

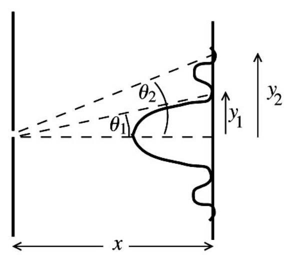

Figure 36.11b

EXECUTE: $w = y_2 - y_1$.

$y_1 = 5.427\times10^{-3}$ m (part (a)).

$$\sin\theta_2 = \frac{2\lambda}{a} = 3.618\times10^{-3}.$$

$\theta_2 = 3.618\times10^{-3}$ rad.

$y_2 = x\tan\theta_2 = 1.085\times10^{-2}$ m.

$w = y_2 - y_1 = 1.085\times10^{-2}\ \text{m} - 5.427\times10^{-3}\ \text{m} = 5.4\ \text{mm}.$

EVALUATE: The central bright fringe is twice as wide as the other bright fringes.

36.12. **IDENTIFY:** We are dealing with single-slit diffraction.

SET UP: We want the wavelength to double the width of the central maximum on a screen. We cannot use the small-angle approximation in this case. The first dark fringe occurs when $a\sin\theta = \lambda$, $y = R\tan\theta$. Call $\lambda_1 = 120\ \mu\text{m}$ and λ_2 the wavelength we want to find.

EXECUTE: $y_1 = R\tan\theta_1$ gives $\theta_1 = \arctan(\lambda_1/R) = \arctan\dfrac{45.0\ \text{cm}}{150\ \text{cm}} = 16.7°$. $y_2 = 2y_1$, so $y_2 = R\tan\theta_2$ so $\theta_2 = \arctan(\lambda_2/R) = \arctan\dfrac{90.0\ \text{cm}}{150\ \text{cm}} = 31.0°$. At the first dark spots $a\sin\theta = \lambda$ so $\dfrac{a\sin\theta_2}{a\sin\theta_1} = \dfrac{\lambda_2}{\lambda_1}$. This gives $\dfrac{\sin 31.0°}{\sin 16.7°} = \dfrac{\lambda_2}{120\ \mu\text{m}}$. So $\lambda_2 = 215\ \mu\text{m}$.

EVALUATE: Notice that to double the pattern width on the screen we do *not* double the wavelength or the angle θ.

36.13. **IDENTIFY:** The minima are located by $\sin\theta = \dfrac{m\lambda}{a}$. For part (b) apply $I = I_0\left\{\dfrac{\sin[\pi a(\sin\theta)/\lambda]}{\pi a(\sin\theta)/\lambda}\right\}^2$.

SET UP: For the first minimum, $m = 1$. The intensity at $\theta = 0$ is I_0.

EXECUTE: **(a)** $\sin\theta = \dfrac{m\lambda}{a} = \sin 90.0° = 1 = \dfrac{m\lambda}{a} = \dfrac{\lambda}{a}$. Thus $a = \lambda = 580\ \text{nm} = 5.80\times10^{-4}\ \text{mm}.$

(b) Using $I = I_0 \left\{ \frac{\sin[\pi a(\sin\theta)/\lambda]}{\pi a(\sin\theta)/\lambda} \right\}^2$ gives

$$\frac{I}{I_0} = \left\{ \frac{\sin[\pi a(\sin\theta)/\lambda]}{\pi a(\sin\theta)/\lambda} \right\}^2 = \left\{ \frac{\sin[\pi(\sin\pi/4)]}{\pi(\sin\pi/4)} \right\}^2 = 0.128.$$

EVALUATE: If $a = \lambda/2$, for example, then at $\theta = 45°$, $\frac{I}{I_0} = \left\{ \frac{\sin[(\pi/2)(\sin\pi/4)]}{(\pi/2)(\sin\pi/4)} \right\}^2 = 0.65$. As a/λ decreases, the screen becomes more uniformly illuminated.

36.14. IDENTIFY: $I = I_0 \left(\frac{\sin(\beta/2)}{\beta/2} \right)^2$. $\beta = \frac{2\pi}{\lambda} a \sin\theta$.

SET UP: The angle θ is small, so $\sin\theta \approx \tan\theta \approx y/x$.

EXECUTE: $\beta = \frac{2\pi a}{\lambda} \sin\theta \approx \frac{2\pi a}{\lambda} \frac{y}{x} = \frac{2\pi(4.50\times10^{-4}\text{ m})}{(6.20\times10^{-7}\text{ m})(3.00\text{ m})} y = (1520\text{ m}^{-1})y$.

(a) $y = 1.00\times10^{-3}$ m: $\frac{\beta}{2} = \frac{(1520\text{ m}^{-1})(1.00\times10^{-3}\text{ m})}{2} = 0.760$.

$$\Rightarrow I = I_0 \left(\frac{\sin(\beta/2)}{\beta/2} \right)^2 = I_0 \left(\frac{\sin(0.760)}{0.760} \right)^2 = 0.822 I_0.$$

(b) $y = 3.00\times10^{-3}$ m: $\frac{\beta}{2} = \frac{(1520\text{ m}^{-1})(3.00\times10^{-3}\text{ m})}{2} = 2.28$.

$$\Rightarrow I = I_0 \left(\frac{\sin(\beta/2)}{\beta/2} \right)^2 = I_0 \left(\frac{\sin(2.28)}{2.28} \right)^2 = 0.111 I_0.$$

(c) $y = 5.00\times10^{-3}$ m: $\frac{\beta}{2} = \frac{(1520\text{ m}^{-1})(5.00\times10^{-3}\text{ m})}{2} = 3.80$.

$$\Rightarrow I = I_0 \left(\frac{\sin(\beta/2)}{\beta/2} \right)^2 = I_0 \left(\frac{\sin(3.80)}{3.80} \right)^2 = 0.0259 I_0.$$

EVALUATE: The first minimum occurs at $y_1 = \frac{\lambda x}{a} = \frac{(6.20\times10^{-7}\text{ m})(3.00\text{ m})}{4.50\times10^{-4}\text{ m}} = 4.1\text{ mm}$. The distances in parts (a) and (b) are within the central maximum. $y = 5.00$ mm is within the first secondary maximum.

36.15. IDENTIFY: The space between the skyscrapers behaves like a single slit and diffracts the radio waves.

SET UP: Cancellation of the waves occurs when $a \sin\theta = m\lambda$, $m = 1, 2, 3, \ldots$, and the intensity of the waves is given by $I_0 \left(\frac{\sin\beta/2}{\beta/2} \right)^2$, where $\beta/2 = \frac{\pi a \sin\theta}{\lambda}$.

EXECUTE: **(a)** First find the wavelength of the waves:

$\lambda = c/f = (3.00\times10^8\text{ m/s})/(88.9\text{ MHz}) = 3.375\text{ m}$.

For no signal, $a \sin\theta = m\lambda$.

$m = 1$: $\sin\theta_1 = (1)(3.375\text{ m})/(15.0\text{ m}) \Rightarrow \theta_1 = \pm 13.0°$.

$m = 2$: $\sin\theta_2 = (2)(3.375\text{ m})/(15.0\text{ m}) \Rightarrow \theta_2 = \pm 26.7°$.

$m = 3$: $\sin\theta_3 = (3)(3.375\text{ m})/(15.0\text{ m}) \Rightarrow \theta_3 = \pm 42.4°$.

$m = 4$: $\sin\theta_4 = (4)(3.375\text{ m})/(15.0\text{ m}) \Rightarrow \theta_4 = \pm 64.1°$.

(b) $I_0\left(\dfrac{\sin\beta/2}{\beta/2}\right)^2$, where $\beta/2=\dfrac{\pi a\sin\theta}{\lambda}=\dfrac{\pi(15.0\text{ m})\sin(5.00°)}{3.375\text{ m}}=1.217\text{ rad}.$

$I=(3.50\text{ W/m}^2)\left[\dfrac{\sin(1.217\text{ rad})}{1.217\text{ rad}}\right]^2=2.08\text{ W/m}^2.$

EVALUATE: The wavelength of the radio waves is very long compared to that of visible light, but it is still considerably shorter than the distance between the buildings.

36.16. **IDENTIFY:** The intensity on the screen varies as the light spreads out (diffracts) after passing through the single slit.

SET UP: $I=I_0\left[\dfrac{\sin(\beta/2)}{\beta/2}\right]^2$ where $\beta=\dfrac{2\pi}{\lambda}a\sin\theta.$

EXECUTE: $\beta=\dfrac{2\pi}{\lambda}a\sin\theta=\left(\dfrac{2\pi}{592\times10^{-9}\text{ m}}\right)(0.0290\times10^{-3}\text{ m})(\sin 1.20°)=6.44589\text{ rad}.$

$I=I_0\left[\dfrac{\sin(\beta/2)}{\beta/2}\right]^2=(4.00\times10^{-5}\text{ W/m}^2)\left[\dfrac{\sin(6.44589\text{ rad})}{6.44589\text{ rad}}\right]^2=2.54\times10^{-8}\text{ W/m}^2.$

EVALUATE: The intensity is less than 1/1500 of the intensity of the light at the center of the central maximum.

36.17. **IDENTIFY:** In this problem we combine double-slit interference with single-slit diffraction.
SET UP: Let D signify a double-slit effect and S signify a single-slit effect. The phases are

$\phi_D=344°,\ \phi_S=172°.\ \ I=I_0\cos^2(\phi/2)\left(\dfrac{\sin\beta/2}{\beta/2}\right)^2.$

EXECUTE: **(a)** We want to relate the slit width a to the slit spacing d. $\dfrac{\phi_D}{360°}=\dfrac{344°}{360°}=\dfrac{d\sin\theta}{\lambda}$ and $\dfrac{\phi_S}{360°}=\dfrac{172°}{360°}=\dfrac{a\sin\theta}{\lambda}$. Taking the ratio gives $\dfrac{344°/360°}{172°/360°}=\dfrac{d\sin\theta/\lambda}{a\sin\theta/\lambda}=\dfrac{d}{a}$, so $d=2a$.

(b) We want the intensity at $\theta=22.0°$. Use $I=I_0\cos^2(\phi/2)\left(\dfrac{\sin\beta/2}{\beta/2}\right)^2$. ϕ is the phase difference for double-slit interference, so $\phi=344°$. β is the phase difference for single-slit diffraction, so $\beta=172°=3.00$ rad. Using $I=I_0\cos^2(\phi/2)\left(\dfrac{\sin\beta/2}{\beta/2}\right)^2$ gives

$I=(0.234\text{ W/m}^2)\cos^2(344°/2)\left(\dfrac{\sin(172°/2)}{(3.00\text{ rad})/2}\right)^2=0.101\text{ W/m}^2.$

EVALUATE: The overall intensity is due to diffraction by each slit and interference of the light from the two slits.

36.18. **IDENTIFY:** The intensity at the screen is due to a combination of single-slit diffraction and double-slit interference.

SET UP: $I=I_0\left(\cos^2\dfrac{\phi}{2}\right)\left[\dfrac{\sin(\beta/2)}{\beta/2}\right]^2$, where $\phi=\dfrac{2\pi d}{\lambda}\sin\theta$ and $\beta=\dfrac{2\pi}{\lambda}a\sin\theta.$

EXECUTE: $\tan\theta=\dfrac{9.00\times10^{-4}\text{ m}}{0.750\text{ m}}=1.200\times10^{-3}$. θ is small, so $\sin\theta\approx\tan\theta.$

$\phi=\dfrac{2\pi d}{\lambda}\sin\theta=\dfrac{2\pi(0.640\times10^{-3}\text{ m})}{568\times10^{-9}\text{ m}}(1.200\times10^{-3})=8.4956\text{ rad}.$

$$\beta = \frac{2\pi a}{\lambda}\sin\theta = \frac{2\pi(0.434\times10^{-3}\text{ m})}{568\times10^{-9}\text{ m}}(1.200\times10^{-3}) = 5.7611\text{ rad.}$$

$$I = (5.00\times10^{-4}\text{ W/m}^2)(\cos 4.2478\text{ rad})^2\left[\frac{\sin 2.8805\text{ rad}}{2.8805}\right]^2 = 8.06\times10^{-7}\text{ W/m}^2.$$

EVALUATE: The intensity as decreased by a factor of almost a thousand, so it would be difficult to see the light at the screen.

36.19. **(a) IDENTIFY** and **SET UP:** The interference fringes (maxima) are located by $d\sin\theta = m\lambda$, with $m = 0, \pm1, \pm2, \ldots$. The intensity I in the diffraction pattern is given by $I = I_0\left(\frac{\sin\beta/2}{\beta/2}\right)^2$, with $\beta = \left(\frac{2\pi}{\lambda}\right)a\sin\theta$. We want $m = \pm3$ in the first equation to give θ that makes $I = 0$ in the second equation.

EXECUTE: $d\sin\theta = m\lambda$ gives $\beta = \left(\frac{2\pi}{\lambda}\right)a\left(\frac{3\lambda}{d}\right) = 2\pi(3a/d)$.

$I = 0$ says $\frac{\sin\beta/2}{\beta/2} = 0$ so $\beta = 2\pi$ and then $2\pi = 2\pi(3a/d)$ and $(d/a) = 3$.

(b) IDENTIFY and **SET UP:** Fringes $m = 0, \pm1, \pm2$ are within the central diffraction maximum and the $m = \pm3$ fringes coincide with the first diffraction minimum. Find the value of m for the fringes that coincide with the second diffraction minimum.

EXECUTE: Second minimum implies $\beta = 4\pi$.

$$\beta = \left(\frac{2\pi}{\lambda}\right)a\sin\theta = \left(\frac{2\pi}{\lambda}\right)a\left(\frac{m\lambda}{d}\right) = 2\pi m(a/d) = 2\pi(m/3).$$

Then $\beta = 4\pi$ says $4\pi = 2\pi(m/3)$ and $m = 6$. Therefore the $m = \pm4$ and $m = +5$ fringes are contained within the first diffraction maximum on one side of the central maximum; two fringes.

EVALUATE: The central maximum is twice as wide as the other maxima so it contains more fringes.

36.20. **IDENTIFY:** The net intensity is the *product* of the factor due to single-slit diffraction and the factor due to double slit interference.

SET UP: The double-slit factor is $I_{DS} = I_0\left(\cos^2\frac{\phi}{2}\right)$ and the single-slit factor is $I_{SS} = \left(\frac{\sin\beta/2}{\beta/2}\right)^2$.

EXECUTE: **(a)** $d\sin\theta = m\lambda \Rightarrow \sin\theta = m\lambda/d$.

$\sin\theta_1 = \lambda/d, \sin\theta_2 = 2\lambda/d, \sin\theta_3 = 3\lambda/d, \sin\theta_4 = 4\lambda/d$.

(b) At the interference bright fringes, $\cos^2\phi/2 = 1$ and $\beta/2 = \frac{\pi a\sin\theta}{\lambda} = \frac{\pi(d/3)\sin\theta}{\lambda}$.

At θ_1, $\sin\theta_1 = \lambda/d$, so $\beta/2 = \frac{\pi(d/3)(\lambda/d)}{\lambda} = \pi/3$. The intensity is therefore

$$I_1 = I_0\left(\cos^2\frac{\phi}{2}\right)\left(\frac{\sin\beta/2}{\beta/2}\right)^2 = I_0(1)\left(\frac{\sin\pi/3}{\pi/3}\right)^2 = 0.684\,I_0.$$

At θ_2, $\sin\theta_2 = 2\lambda/d$, so $\beta/2 = \frac{\pi(d/3)(2\lambda/d)}{\lambda} = 2\pi/3$. Using the same procedure as for θ_1, we have

$$I_2 = I_0(1)\left(\frac{\sin 2\pi/3}{2\pi/3}\right)^2 = 0.171\,I_0.$$

At θ_3, we get $\beta/2 = \pi$, which gives $I_3 = 0$ since $\sin\,\pi = 0$.

At θ_4, $\sin\,\theta_4 = 4\lambda/d$, so $\beta/2 = 4\pi/3$, which gives $I_4 = I_0\left(\dfrac{\sin 4\pi/3}{4\pi/3}\right)^2 = 0.0427\,I_0$.

(c) Since $d = 3a$, every third interference maximum is missing.

(d) In Figure 36.12c in the textbook, every fourth interference maximum at the sides is missing because $d = 4a$.

EVALUATE: The result in this problem is different from that in Figure 36.12c in the textbook because in this case $d = 3a$, so every third interference maximum at the sides is missing. Also the "envelope" of the intensity function decreases more rapidly here than in Figure 36.12c in the text because the first diffraction minimum is reached sooner, and the decrease in intensity from one interference maximum to the next is faster for $a = d/3$ than for $a = d/4$.

36.21. **(a) IDENTIFY** and **SET UP:** If the slits are very narrow then the central maximum of the diffraction pattern for each slit completely fills the screen and the intensity distribution is given solely by the two-slit interference. The maxima are given by $d\sin\theta = m\lambda$ so $\sin\theta = m\lambda/d$. Solve for θ.

EXECUTE: 1st order maximum: $m = 1$, so $\sin\theta = \dfrac{\lambda}{d} = \dfrac{580\times10^{-9}\text{ m}}{0.530\times10^{-3}\text{ m}} = 1.094\times10^{-3}$; $\theta = 0.0627°$.

2nd order maximum: $m = 2$, so $\sin\theta = \dfrac{2\lambda}{d} = 2.188\times10^{-3}$; $\theta = 0.125°$.

(b) IDENTIFY and **SET UP:** The intensity is given by Eq. (36.12): $I = I_0\cos^2(\phi/2)\left(\dfrac{\sin\beta/2}{\beta/2}\right)^2$.

Calculate ϕ and β at each θ from part (a).

EXECUTE: $\phi = \left(\dfrac{2\pi d}{\lambda}\right)\sin\theta = \left(\dfrac{2\pi d}{\lambda}\right)\left(\dfrac{m\lambda}{d}\right) = 2\pi m$, so $\cos^2(\phi/2) = \cos^2(m\pi) = 1$.

(Since the angular positions in part (a) correspond to interference maxima.)

$$\beta = \left(\frac{2\pi a}{\lambda}\right)\sin\theta = \left(\frac{2\pi a}{\lambda}\right)\left(\frac{m\lambda}{d}\right) = 2\pi m(a/d) = m2\pi\left(\frac{0.320\text{ mm}}{0.530\text{ mm}}\right) = m(3.794\text{ rad}).$$

1st order maximum: $m = 1$, so $I = I_0(1)\left(\dfrac{\sin(3.794/2)\text{rad}}{(3.794/2)\text{rad}}\right)^2 = 0.249I_0$.

2nd order maximum: $m = 2$, so $I = I_0(1)\left(\dfrac{\sin 3.794\text{ rad}}{3.794\text{ rad}}\right)^2 = 0.0256I_0$.

EVALUATE: The first diffraction minimum is at an angle θ given by $\sin\theta = \lambda/a$ so $\theta = 0.104°$. The first order fringe is within the central maximum and the second order fringe is inside the first diffraction maximum on one side of the central maximum. The intensity here at this second fringe is much less than I_0.

36.22. **IDENTIFY:** The diffraction minima are located by $\sin\theta = \dfrac{m_\text{d}\lambda}{a}$ and the two-slit interference maxima are located by $\sin\theta = \dfrac{m_\text{i}\lambda}{d}$. The third bright band is missing because the first order single-slit minimum occurs at the same angle as the third order double-slit maximum.

SET UP: The pattern is sketched in Figure 36.22. $\tan\theta = \dfrac{3\text{ cm}}{90\text{ cm}}$, so $\theta = 1.91°$.

EXECUTE: Single-slit dark spot: $a\sin\theta = \lambda$ and

$$a = \frac{\lambda}{\sin\theta} = \frac{500\text{ nm}}{\sin 1.91°} = 1.50\times10^4\text{ nm} = 15.0\ \mu\text{m (width)}.$$

<u>Double-slit bright fringe</u>: $d\sin\theta = 3\lambda$ and

$$d = \frac{3\lambda}{\sin\theta} = \frac{3(500\text{ nm})}{\sin 1.91°} = 4.50\times 10^4\text{ nm} = 45.0\ \mu\text{m (separation).}$$

EVALUATE: Note that $d/a = 3.0$.

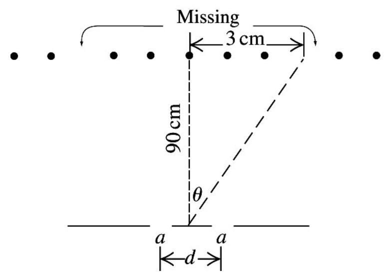

Figure 36.22

36.23. IDENTIFY: We combine double-slit interference with single-slit diffraction.

SET UP: Single-slit dark spots: $a\sin\theta_m = m\lambda$, double-slit bright spots: $d\sin\theta_m = m\lambda$. We want to find the slit width a.

EXECUTE: (a) The m = 3 double-slit bright spot is missing because it lies where the single-slit intensity is zero. For single slit dark spot $a\sin\theta_k = k\lambda$ and for double slit bright spot $d\sin\theta_m = m\lambda$. The minimum a occurs for the minimum k, which is 1. Thus $a\sin\theta = \lambda$ (single slit) and $d\sin\theta = 3\lambda$ (double slit). Dividing gives $a/d = 1/3$, so $a = d/3 = (9.00\text{ mm})/3 = 3.00$ mm.

(b) For the next larger a, we use $k = 2$, so $a\sin\theta = 2\lambda$ and $d\sin\theta = 3\lambda$. Dividing gives $a/d = 2/3$, which gives $a = 2/3\ d = 6.00$ mm.

EVALUATE: It is also possible for a double-slit minimum to cancel a single-slit maximum.

36.24. IDENTIFY: This problem involves the intensity of a single-slit and double-slit pattern.

SET UP: $I = I_0\cos^2(\phi/2)\left(\dfrac{\sin\beta/2}{\beta/2}\right)^2$, $\beta = \dfrac{2\pi a\sin\theta}{\lambda}$, $\phi = \dfrac{2\pi d\sin\theta}{\lambda}$, $a\sin\theta_m = m\lambda$ (single-slit minima), $d\sin\theta_m = m\lambda$ (double-slit maxima). We want I_1/I_2 for the maxima.

EXECUTE: The double-slit m = 5 maximum is missing because it lies at a minimum for the single-slit diffraction pattern. Since the double-slit m = 0 through m = 4 maxima are present, the single-slit minimum must be the first one. Thus $a\sin\theta = \lambda$ and $d\sin\theta = 5\lambda$. Dividing gives $a/d = 1/5$, so $a = d/5 = 0.200$ mm.

<u>At $m = 1$</u>: $d\sin\theta = \lambda$, so $\dfrac{\phi_1}{2} = \dfrac{\pi d\sin\theta}{\lambda} = \pi$. $\dfrac{\beta_1}{2} = \dfrac{\pi a\sin\theta}{\lambda} = \dfrac{\pi(d/5)\sin\theta}{\lambda} = \pi/5 = 36.0°$. Therefore

$$I_1 = I_0\cos^2(\phi/2)\left(\frac{\sin\beta/2}{\beta/2}\right)^2 = I_0\cos^2(\pi)\left(\frac{\sin 36.0°}{\pi/5}\right)^2 = 0.8751 I_0.$$

<u>At $m = 2$</u>: $d\sin\theta = 2\lambda$, so $\dfrac{\phi_2}{2} = \dfrac{\pi d\sin\theta}{\lambda} = 2\pi$. $\dfrac{\beta_2}{2} = \dfrac{\pi a\sin\theta}{\lambda} = \dfrac{\pi(d/5)\sin\theta}{\lambda} = 2\pi/5 = 72.0°$. Thus

$$I_2 = I_0\cos^2(2\pi)\left(\frac{\sin 72.0°}{2\pi/5}\right)^2 = 0.5728 I_0.$$

$$\frac{I_1}{I_2} = \frac{0.8751 I_0}{0.5728 I_0} = 1.53.$$

EVALUATE: $I_1 > I_2$ because the maxima get dimmer as we move away from the center.

36.25. **IDENTIFY:** Knowing the wavelength of the light and the location of the first interference maxima, we can calculate the line density of the grating.

SET UP: The line density in lines/cm is $1/d$, with d in cm. The bright spots are located by $d\sin\theta = m\lambda,\ m = 0, \pm 1, \pm 2, \ldots$.

EXECUTE: **(a)** $d = \dfrac{m\lambda}{\sin\theta} = \dfrac{(1)(632.8\times10^{-9}\ \text{m})}{\sin 17.8°} = 2.07\times10^{-6}\ \text{m} = 2.07\times10^{-4}\ \text{cm}.\ \dfrac{1}{d} = 4830\ \text{lines/cm}.$

(b) $\sin\theta = \dfrac{m\lambda}{d} = m\left(\dfrac{632.8\times10^{-9}\ \text{m}}{2.07\times10^{-6}\ \text{m}}\right) = m(0.3057).$ For $m = \pm 2,\ \theta = \pm 37.7°.$ For $m = \pm 3,\ \theta = \pm 66.5°.$

EVALUATE: The angles are large, so they are not equally spaced; $37.7° \neq 2(17.8°)$ and $66.5° \neq 3(17.8°)$.

36.26. **IDENTIFY:** The maxima are located by $d\sin\theta = m\lambda.$

SET UP: The order corresponds to the values of m.

EXECUTE: <u>First-order:</u> $d\sin\theta_1 = \lambda.$ <u>Fourth-order:</u> $d\sin\theta_4 = 4\lambda.$

$\dfrac{d\sin\theta_4}{d\sin\theta_1} = \dfrac{4\lambda}{\lambda},\ \sin\theta_4 = 4\sin\theta_1 = 4\sin 11.3°$ and $\theta_4 = 51.6°.$

EVALUATE: We did not have to solve for d.

36.27. **IDENTIFY:** This problem is about a diffraction grating.

SET UP: Bright fringes occur when $d\sin\theta_m = m\lambda$. Dark fringes occur when $a\sin\theta_m = m\lambda$.

EXECUTE: **(a)** We want d. The 4th order bright spot should occur at 66.6°, so $d\sin\theta_m = m\lambda$ gives $d\sin 66.6° = 4(550\ \text{nm})$. So $d = 2.40\ \mu\text{m}$.

(b) We want the line density. The density is $1/d = 1/(2.40\ \mu\text{m}) = 417$ slits/mm.

(c) We want the width a of each slit. $a\sin\theta_m = m\lambda$ gives $a\sin 66.6° = 3(550\ \text{nm})$, so $a = 1.80\ \mu\text{m}$.

EVALUATE: The width of the slits is 1.80/2.40 = 0.750 times the slit spacing, so single-slit diffraction certainly plays a role.

36.28. **IDENTIFY:** The bright spots are located by $d\sin\theta = m\lambda.$

SET UP: Third-order means $m = 3$ and second-order means $m = 2.$

EXECUTE: $\dfrac{m\lambda}{\sin\theta} = d = \text{constant},$ so $\dfrac{m_r\lambda_r}{\sin\theta_r} = \dfrac{m_v\lambda_v}{\sin\theta_v}.$

$\sin\theta_v = \sin\theta_r\left(\dfrac{m_v}{m_r}\right)\left(\dfrac{\lambda_v}{\lambda_r}\right) = (\sin 65.0°)\left(\dfrac{2}{3}\right)\left(\dfrac{400\ \text{nm}}{700\ \text{nm}}\right) = 0.345$ and $\theta_v = 20.2°.$

EVALUATE: The third-order line for a particular λ occurs at a larger angle than the second-order line. In a given order, the line for violet light (400 nm) occurs at a smaller angle than the line for red light (700 nm).

36.29. **IDENTIFY:** This problem involves the resolving power of a diffraction grating.

SET UP: $R = \dfrac{\lambda}{\Delta\lambda} = mN$.

EXECUTE: **(a)** We want R_{min}. $R_{min} = \dfrac{\lambda}{\Delta\lambda} = \dfrac{430.790\ \text{nm} - 430.774\ \text{nm}}{430.774\ \text{nm}} = 2.69\times10^4.$

(b) We want the lowest order needed. $R = Nm$ gives $m = R/N$ = 26,900/12,800 = 2.10. So $m = 2$ is not quite enough to resolve these lines, but $m = 3$ will do it. So the third-order is the lowest.

EVALUATE: More lines would allow a lower order. In this case, 13,500 lines would allow $m = 2$ because 26,900/13,600 = 1.98, which is less than 2.

36.30. IDENTIFY: The maxima are located by $d\sin\theta = m\lambda$.

SET UP: 350 slits/mm $\Rightarrow d = \dfrac{1}{3.50\times10^{5}\ \text{m}^{-1}} = 2.857\times10^{-6}$ m. The visible spectrum is between approximately 380 nm and 750 nm.

EXECUTE: **(a)** $m = 1$: $\theta_{380} = \arcsin\left(\dfrac{\lambda}{d}\right) = \arcsin\left(\dfrac{3.80\times10^{-7}\ \text{m}}{2.857\times10^{-6}\ \text{m}}\right) = 6.643°$.

$\theta_{750} = \arcsin\left(\dfrac{\lambda}{d}\right) = \arcsin\left(\dfrac{7.50\times10^{-7}\ \text{m}}{2.857\times10^{-6}\ \text{m}}\right) = 15.2185°$. $\Delta\theta_1 = 15.2185° - 6.643° = 8.58°$.

(b) $m = 3$: $\theta_{380} = \arcsin\left(\dfrac{3\lambda}{d}\right) = \arcsin\left(\dfrac{3(3.80\times10^{-7}\ \text{m})}{2.857\times10^{-6}\ \text{m}}\right) = 23.516°$.

$\theta_{750} = \arcsin\left(\dfrac{3\lambda}{d}\right) = \arcsin\left(\dfrac{3(7.50\times10^{-7}\ \text{m})}{2.857\times10^{-6}\ \text{m}}\right) = 51.952°$. $\Delta\theta_1 = 51.952° - 23.516° = 28.4°$.

EVALUATE: $\Delta\theta$ is larger in third order.

36.31. IDENTIFY: The maxima are located by $d\sin\theta = m\lambda$.

SET UP: 5000 slits/cm $\Rightarrow d = \dfrac{1}{5.00\times10^{5}\ \text{m}^{-1}} = 2.00\times10^{-6}$ m.

EXECUTE: **(a)** $\lambda = \dfrac{d\sin\theta}{m} = \dfrac{(2.00\times10^{-6}\ \text{m})\sin 13.5°}{1} = 4.67\times10^{-7}$ m.

(b) $m = 2$: $\theta = \arcsin\left(\dfrac{m\lambda}{d}\right) = \arcsin\left(\dfrac{2(4.67\times10^{-7}\ \text{m})}{2.00\times10^{-6}\ \text{m}}\right) = 27.8°$.

EVALUATE: Since the angles are fairly small, the second-order deviation is approximately twice the first-order deviation.

36.32. IDENTIFY: The grooves in a CD and DVD form a reflection diffraction grating. Constructive interference when $d\sin\theta = m\lambda$.

SET UP: The maxima are located by $d\sin\theta = m\lambda$, where $d = 1.60\times10^{-6}$ m for a CD and $d = 0.740\times10^{-6}$ m for a DVD.

EXECUTE: **(a)** For a CD we have: $\theta = \arcsin\left(\dfrac{m\lambda}{d}\right) = \arcsin\left(\dfrac{m(6.328\times10^{-7}\ \text{m})}{1.60\times10^{-6}\ \text{m}}\right) = \arcsin(0.396m)$.

For $m = 1$ we have $\theta_1 = 23.3°$. For $m = 2$ we have $\theta_2 = 52.3°$. There are no other maxima.

(b) For a DVD we have: $\theta = \arcsin\left(\dfrac{m\lambda}{d}\right) = \arcsin\left(\dfrac{m(6.328\times10^{-7}\ \text{m})}{0.740\times10^{-6}\ \text{m}}\right) = \arcsin(0.855m)$. For $m = 1$ we have $\theta_1 = 58.8°$. There are no other maxima.

EVALUATE: The reflective surface produces the same interference pattern as a grating with slit separation d.

36.33. IDENTIFY: The resolution is described by $R = \dfrac{\lambda}{\Delta\lambda} = Nm$. Maxima are located by $d\sin\theta = m\lambda$.

SET UP: For 500 slits/mm, $d = (500\ \text{slits/mm})^{-1} = (500{,}000\ \text{slits/m})^{-1}$.

EXECUTE: **(a)** $N = \dfrac{\lambda}{m\Delta\lambda} = \dfrac{6.5645\times10^{-7}\ \text{m}}{2(6.5645\times10^{-7}\ \text{m} - 6.5627\times10^{-7}\ \text{m})} = 1820$ slits.

(b) $\theta = \sin^{-1}\left(\dfrac{m\lambda}{d}\right) \Rightarrow \theta_1 = \sin^{-1}((2)(6.5645\times10^{-7}\text{ m})(500{,}000\text{ m}^{-1})) = 41.0297°$ and

$\theta_2 = \sin^{-1}((2)(6.5627\times10^{-7}\text{ m})(500{,}000\text{ m}^{-1})) = 41.0160°$. $\Delta\theta = 0.0137°$.

EVALUATE: $d\cos\theta\, d\theta = \lambda/N$, so for 1820 slits the angular interval $\Delta\theta$ between each of these maxima and the first adjacent minimum is $\Delta\theta = \dfrac{\lambda}{Nd\cos\theta} = \dfrac{6.56\times10^{-7}\text{ m}}{(1820)(2.0\times10^{-6}\text{ m})\cos41°} = 0.0137°$. This is the same as the angular separation of the maxima for the two wavelengths and 1820 slits is just sufficient to resolve these two wavelengths in second order.

36.34. **IDENTIFY:** The maxima are given by $2d\sin\theta = m\lambda$, $m = 1, 2, \ldots$.

SET UP: $d = 3.50\times10^{-10}$ m.

EXECUTE: **(a)** Using $m = 1$ gives

$\lambda = \dfrac{2d\sin\theta}{m} = 2(3.50\times10^{-10}\text{ m})\sin22.0° = 2.62\times10^{-10}\text{ m} = 0.262\text{ nm} = 262\text{ pm}$. This is an x ray.

(b) $\sin\theta = m\left(\dfrac{\lambda}{2d}\right) = m\left(\dfrac{2.62\times10^{-10}\text{ m}}{2(3.50\times10^{-10}\text{ m})}\right) = 0.3743m$. $m = 2$: $\theta = 48.5°$. The equation doesn't have any solutions for $m > 2$.

EVALUATE: In this problem $\lambda/d = 0.75$.

36.35. **IDENTIFY** and **SET UP:** The maxima occur at angles θ given by $2d\sin\theta = m\lambda$, where *d* is the spacing between adjacent atomic planes. Solve for *d*.

EXECUTE: Second order says $m = 2$.

$d = \dfrac{m\lambda}{2\sin\theta} = \dfrac{2(0.0850\times10^{-9}\text{ m})}{2\sin21.5°} = 2.32\times10^{-10}\text{ m} = 0.232\text{ nm}$.

EVALUATE: Our result is similar to *d* calculated in Example 36.5.

36.36. **IDENTIFY:** The crystal behaves like a diffraction grating.

SET UP: The maxima are at angles θ given by $2d\sin\theta = m\lambda$, where $d = 0.440$ nm.

EXECUTE: $m = 1$. $\lambda = \dfrac{2d\sin\theta}{1} = 2(0.440\text{ nm})\sin39.4° = 0.559\text{ nm}$.

EVALUATE: The result is a reasonable x-ray wavelength.

36.37. **IDENTIFY** and **SET UP:** The angular size of the first dark ring is given by $\sin\theta_1 = 1.22\lambda/D$. Calculate θ_1, and then the diameter of the ring on the screen is $2(4.5\text{ m})\tan\theta_1$.

EXECUTE: $\sin\theta_1 = 1.22\left(\dfrac{620\times10^{-9}\text{ m}}{7.4\times10^{-6}\text{ m}}\right) = 0.1022$; $\theta_1 = 0.1024$ rad.

The radius of the Airy disk (central bright spot) is $r = (4.5\text{ m})\tan\theta_1 = 0.462$ m. The diameter is $2r = 0.92\text{ m} = 92\text{ cm}$.

EVALUATE: $\lambda/D = 0.084$. For this small *D* the central diffraction maximum is broad.

36.38. **IDENTIFY** and **SET UP:** For the first dark ring, $\sin\theta_1 = 1.22\dfrac{\lambda}{D}$ and for the second dark ring $\sin\theta_2 = 2.23\dfrac{\lambda}{D}$. If *y* is the distance from the center to the ring, we can use the small-angle approximation because *x* << *y*, where *x* is the distance from the aperture to the screen. Therefore $\sin\theta \approx \tan\theta = y/x$. The difference in radii of the first two dark rings is 1.65 mm.

EXECUTE: The radius of the first dark ring is $y_1 = x\tan\theta_1 = x(1.22\,\lambda/D)$. The radius of the second ring is $y_2 = x\tan\theta_2 = x(1.22\,\lambda/D)$. Dividing these two equations gives $y_2/y_1 = 2.23/1.22 = 1.8279$, so $y_2 = 1.8279y_1$. We are told that the difference in radii is 1.65 mm, so $y_2 - y_1 = 1.65$ mm. Substituting for y_2 gives $1.8279y_1 - y_1 = 1.65$ mm, so $y_1 = 1.9931$ mm. Now find D using $y_1 = x(1.22\,\lambda/D)$.

1.9931×10^{-3} m = (1.20 m)(1.22)(490 nm)/D, so $D = 3.60\times10^5$ nm = 3.60×10^{-4} m = 0.360 mm.

EVALUATE: This is about the diameter of a good-sized pinhole.

36.39. **IDENTIFY:** Apply $\sin\theta = 1.22\dfrac{\lambda}{D}$.

SET UP: $\theta = \dfrac{W}{h}$, where $W = 28\text{ km}$ and $h = 1200\text{ km}$. θ is small, so $\sin\theta \approx \theta$.

EXECUTE: $D = \dfrac{1.22\lambda}{\sin\theta} = 1.22\lambda\dfrac{h}{W} = 1.22(0.036\text{ m})\dfrac{1.2\times10^6\text{ m}}{2.8\times10^4\text{ m}} = 1.88\text{ m}.$

EVALUATE: D must be significantly larger than the wavelength, so a much larger diameter is needed for microwaves than for visible wavelengths.

36.40. **IDENTIFY:** Apply $\sin\theta = 1.22\dfrac{\lambda}{D}$.

SET UP: $\theta = (1/60)°$.

EXECUTE: $D = \dfrac{1.22\lambda}{\sin\theta} = \dfrac{1.22(5.5\times10^{-7}\text{ m})}{\sin(1/60)°} = 2.31\times10^{-3}\text{ m} = 2.3\text{ mm}.$

EVALUATE: The larger the diameter the smaller the angle that can be resolved.

36.41. **IDENTIFY:** The diameter D of the mirror determines the resolution.

SET UP: The resolving power is $\theta_{\text{res}} = 1.22\dfrac{\lambda}{D}$.

EXECUTE: The same θ_{res} means that $\dfrac{\lambda_1}{D_1} = \dfrac{\lambda_2}{D_2}$. $D_2 = D_1\dfrac{\lambda_2}{\lambda_1} = (8000\times10^3\text{ m})\left(\dfrac{550\times10^{-9}\text{ m}}{2.0\times10^{-2}\text{ m}}\right) = 220\text{ m}.$

EVALUATE: The Hubble telescope has an aperture of 2.4 m, so this would have to be an *enormous* optical telescope!

36.42. **IDENTIFY:** Rayleigh's criterion limits the angular resolution.

SET UP: Rayleigh's criterion is $\sin\theta \approx \theta = 1.22\lambda/D$. Call R = 11.5 m = the distance from the bear to the lens.

EXECUTE: **(a)** Using Rayleigh's criterion

$\sin\theta \approx \theta = 1.22\lambda/D = (1.22)(550\text{ nm})/(135/4\text{ mm}) = 1.99\times10^{-5}\text{ rad}.$

On the bear this angle subtends a distance x. Using $\theta = x/R$ gives

$x = R\theta = (11.5\text{ m})(1.99\times10^{-5}\text{ rad}) = 2.29\times10^{-4}\text{m} = 0.23\text{ mm}.$

(b) At $f/22$, D is $4/22$ times as large as at $f/4$. Since θ is proportional to $1/D$, and x is proportional to θ, x is $1/(4/22) = 22/4$ times as large as it was at $f/4$. $x = (0.229\text{ mm})(22/4) = 1.3\text{ mm}.$

EVALUATE: A wide-angle lens, such as one having a focal length of 28 mm, would have a much smaller opening at $f/2$ and hence would have an even less resolving ability.

36.43. **IDENTIFY** and **SET UP:** Let y be the separation between the two points being resolved and let s be their distance from the telescope. Then the limit of resolution corresponds to $1.22\,\dfrac{\lambda}{D} = \dfrac{y}{s}$.

EXECUTE: **(a)** Let the two points being resolved be the opposite edges of the crater, so y is the diameter of the crater. For the moon, $s = 3.8\times10^8$ m. $y = 1.22\lambda s/D$.

Hubble: $D = 2.4$ m and $\lambda = 380$ nm gives the maximum resolution, so $y = 73$ m.

Arecibo: $D = 305$ m and $\lambda = 0.75$ m; $y = 1.1\times10^{6}$ m.

(b) $s = \dfrac{yD}{1.22\lambda}$. Let $y \approx 0.30$ m (the size of a license plate).

$s = (0.30\text{ m})(2.4\text{ m})/[(1.22)(380\times10^{-9}\text{ m})] = 1600$ km.

EVALUATE: D/λ is much larger for the optical telescope and it has a much larger resolution even though the diameter of the radio telescope is much larger.

36.44. **IDENTIFY** and **SET UP:** Resolved by Rayleigh's criterion means angular separation θ of the objects equals $1.22\lambda/D$. The angular separation θ of the objects is their linear separation divided by their distance from the telescope.

EXECUTE: $\theta = \dfrac{250\times10^{3}\text{ m}}{5.93\times10^{11}\text{ m}}$, where 5.93×10^{11} m is the distance from the earth to Jupiter. Thus $\theta = 4.216\times10^{-7}$ rad.

Then $\theta = 1.22\dfrac{\lambda}{D}$ and $D = \dfrac{1.22\lambda}{\theta} = \dfrac{1.22(500\times10^{-9}\text{ m})}{4.216\times10^{-7}\text{ rad}} = 1.45$ m.

EVALUATE: This is a very large telescope mirror. The greater the angular resolution the greater the diameter the lens or mirror must be.

36.44. **IDENTIFY:** We can apply the equation for single-slit diffraction to the hair, with the thickness of the hair replacing the thickness of the slit.

SET UP: The dark fringes are located by $\sin\theta = m\dfrac{\lambda}{a}$. The first dark fringes are for $m = \pm1$. $y = x\tan\theta$ is the distance from the center of the screen, where $x = 125$ cm is the distance from the hair to the screen. The distance y from the center to one minimum is 2.61 cm.

EXECUTE: $\tan\theta = \dfrac{y}{x} = \dfrac{2.61\text{ cm}}{125\text{ cm}} = 0.02088$ so $\theta = 1.20°$. $a = \dfrac{\lambda}{\sin\theta} = \dfrac{632.8\times10^{-9}\text{ m}}{\sin 1.20°} = 30.2\ \mu$m.

EVALUATE: Although the thickness of human hairs can vary considerably, 30 μm is a reasonable thickness.

36.46. **IDENTIFY:** The two holes behave like double slits and cause the sound waves to interfere after they pass through the holes. The motion of the speakers causes a Doppler shift in the wavelength of the sound.

SET UP: The wavelength of the sound that strikes the wall is $\lambda = \lambda_0 - v_s T_s$, and destructive interference first occurs where $\sin\theta = \lambda/2$.

EXECUTE: **(a)** First find the wavelength of the sound that strikes the openings in the wall.

$\lambda = \lambda_0 - v_s T_s = v/f_s - v_s/f_s = (v - v_s)/f_s = (344\text{ m/s} - 80.0\text{ m/s})/(960\text{ Hz}) = 0.275$ m. Destructive interference first occurs where $d\sin\theta = \lambda/2$, which gives

$d = \lambda/(2\sin\theta) = (0.275\text{ m})/(2\sin 11.4°) = 0.636$ m.

(b) $\lambda = v/f = (344\text{ m/s})/(960\text{ Hz}) = 0.3583$ m.

$\sin\theta = \lambda/2d = (0.3583\text{ m})/[2(0.696\text{ m})] \rightarrow \theta = \pm14.9°$.

EVALUATE: The moving source produces sound of shorter wavelength than the stationary source, so the angles at which destructive interference occurs are smaller for the moving source than for the stationary source.

36.47. **IDENTIFY:** In the single-slit diffraction pattern, the intensity is a maximum at the center and zero at the dark spots. At other points, it depends on the angle at which one is observing the light.

SET UP: Dark fringes occur when $\sin\,\theta_m = m\lambda/a$, where $m = 1,\ 2,\ 3,\ \ldots,$ and the intensity is given by $I_0\left(\dfrac{\sin\beta/2}{\beta/2}\right)^2$, where $\beta/2 = \dfrac{\pi a\sin\theta}{\lambda}$.

EXECUTE: **(a)** At the maximum possible angle, $\theta = 90°$, so

$m_{\text{max}} = (a\sin 90°)/\lambda = (0.0250\text{ mm})/(632.8\text{ nm}) = 39.5.$

Since m must be an integer and $\sin\theta$ must be ≤ 1, $m_{\text{max}} = 39$. The total number of dark fringes is 39 on each side of the central maximum for a total of 78.

(b) The farthest dark fringe is for $m = 39$, giving

$\sin\theta_{39} = (39)(632.8\text{ nm})/(0.0250\text{ mm}) \Rightarrow \theta_{39} = \pm 80.8°.$

(c) The next closer dark fringe occurs at $\sin\theta_{38} = (38)(632.8\text{ nm})/(0.0250\text{ mm}) \Rightarrow \theta_{38} = 74.1°.$

The angle midway these two extreme fringes is $(80.8° + 74.1°)/2 = 77.45°$, and the intensity at this angle is $I = I_0\left(\dfrac{\sin\beta/2}{\beta/2}\right)^2$, where $\beta/2 = \dfrac{\pi a\sin\theta}{\lambda} = \dfrac{\pi(0.0250\text{ mm})\sin(77.45°)}{632.8\text{ nm}} = 121.15\text{ rad}$, which gives

$$I = (8.50\text{W/m}^2)\left[\frac{\sin(121.15\text{ rad})}{121.15\text{ rad}}\right]^2 = 5.55\times10^{-4}\text{ W/m}^2.$$

EVALUATE: At the angle in part (c), the intensity is so low that the light would be barely perceptible.

36.48. **IDENTIFY:** $d = \dfrac{1}{N}$, so the bright fringes are located by $\dfrac{1}{N}\sin\theta = \lambda$.

SET UP: Red: $\dfrac{1}{N}\sin\theta_R = 750\text{ nm}$. Violet: $\dfrac{1}{N}\sin\theta_V = 380\text{ nm}$.

EXECUTE: **(a)** $\dfrac{\sin\theta_R}{\sin\theta_V} = \dfrac{75}{38}$. $\theta_R - \theta_V = 27.0°$, so $\theta_R = \theta_V + 27.0°$. $\dfrac{\sin(\theta_V + 27.0°)}{\sin\theta_V} = \dfrac{75}{38}$. Using the trigonometry identity from Appendix B for the sin of the sum of two angles gives

$$\frac{\sin\theta_V\,\cos 27.0° + \cos\theta_V\,\sin 27.0°}{\sin\theta_V} = \frac{75}{38} \quad\rightarrow\quad \cos 27.0° + \cot\theta_V\sin 27.0° = 75/38.$$

$\tan\theta_V = 0.4193 \Rightarrow \theta_V = 22.75°$ and $\theta_R = \theta_V + 27.0° = 22.75° + 27.0° = 49.75°$.

Using $\dfrac{1}{N}\sin\theta_R = 750\text{ nm}$ gives

$$N = \frac{\sin\theta_R}{750\text{ nm}} = \frac{\sin 49.75°}{750\times10^{-9}\text{ m}} = 1.02\times10^6\text{ lines/m} = 1.02\times10^4\text{ lines/cm}.$$

(b) The spectrum begins at 22.7 ° and ends at 49.7°.

EVALUATE: As N is increased, the angular range of the visible spectrum increases.

36.49. **IDENTIFY** and **SET UP:** $\sin\theta = \lambda/a$ locates the first dark band. In the liquid the wavelength changes and this changes the angular position of the first diffraction minimum.

EXECUTE: $\sin\theta_{\text{air}} = \dfrac{\lambda_{\text{air}}}{a}$; $\sin\theta_{\text{liquid}} = \dfrac{\lambda_{\text{liquid}}}{a}$. $\lambda_{\text{liquid}} = \lambda_{\text{air}}\left(\dfrac{\sin\theta_{\text{liquid}}}{\sin\theta_{\text{air}}}\right) = \lambda_{\text{air}}\dfrac{\sin 21.6°}{\sin 38.2°} = 0.5953\lambda_{\text{air}}$.

$\lambda_{\text{liquid}} = \lambda_{\text{air}}/n$, so $n = \lambda_{\text{air}}/\lambda_{\text{liquid}} = \dfrac{\lambda_{\text{air}}}{0.5953\lambda_{\text{air}}} = 1.68.$

EVALUATE: Light travels faster in air and n must be > 1.00. The smaller λ in the liquid reduces θ that located the first dark band.

36.50. **IDENTIFY:** The wavelength of the light is smaller under water than it is in air, which will affect the resolving power of the lens, by Rayleigh's criterion.

SET UP: The wavelength under water is $\lambda = \lambda_0/n$, and for small angles Rayleigh's criterion is $\theta = 1.22\lambda/D$.

EXECUTE: **(a)** In air the wavelength is $\lambda_0 = c/f = (3.00\times10^8 \text{ m/s})/(6.00\times10^{14} \text{ Hz}) = 5.00\times10^{-7} \text{ m}$. In water the wavelength is $\lambda = \lambda_0/n = (5.00\times10^{-7}\text{ m})/1.33 = 3.76\times10^{-7}\text{ m}$. With the lens open all the way, we have $D = f/2.8 = (35.0 \text{ mm})/2.80 = (0.0350 \text{ m})/2.80$. In the water, we have

$\sin\theta \approx \theta = 1.22\lambda/D = (1.22)(3.76\times10^{-7}\text{ m})[(0.0350 \text{ m})/2.80] = 3.67\times10^{-5} \text{ rad}.$

Calling w the width of the resolvable detail, we have

$\theta = w/x \to w = x\theta = (2750 \text{ mm})(3.67\times10^{-5}\text{ rad}) = 0.101 \text{ mm}.$

(b) $\theta = 1.22\lambda/D = (1.22)(5.00\times10^{-7}\text{ m})/[(0.0350 \text{ m})/2.80] = 4.88\times10^{-5} \text{ rad}.$

$w = x\theta = (2750 \text{ mm})(4.88\times10^{-5} \text{ rad}) = 0.134 \text{ mm}.$

EVALUATE: Due to the reduced wavelength underwater, the resolution of the lens is better under water than in air.

36.51. **IDENTIFY:** $I = I_0\left(\dfrac{\sin\gamma}{\gamma}\right)^2$. The maximum intensity occurs when the derivative of the intensity function with respect to γ is zero.

SET UP: $\dfrac{d\sin\gamma}{d\gamma} = \cos\gamma$. $\dfrac{d}{d\gamma}\left(\dfrac{1}{\gamma}\right) = -\dfrac{1}{\gamma^2}$.

EXECUTE: **(a)**

$$\frac{dI}{d\gamma} = I_0\frac{d}{d\gamma}\left(\frac{\sin\gamma}{\gamma}\right)^2 = 2\left(\frac{\sin\gamma}{\gamma}\right)\left(\frac{\cos\gamma}{\gamma} - \frac{\sin\gamma}{\gamma^2}\right) = 0.\ \frac{\cos\gamma}{\gamma} - \frac{\sin\gamma}{\gamma^2} \Rightarrow \gamma\cos\gamma = \sin\gamma \Rightarrow \gamma = \tan\gamma.$$

(b) The graph in Figure 36.51 is a plot of $f(\gamma) = \gamma - \tan\gamma$. When $f(\gamma)$ equals zero, there is an intensity maximum. Getting estimates from the graph, and then using trial and error to narrow in on the value, we find that the two smallest values of γ are $\gamma = 4.49$ rad and 7.73 rad.

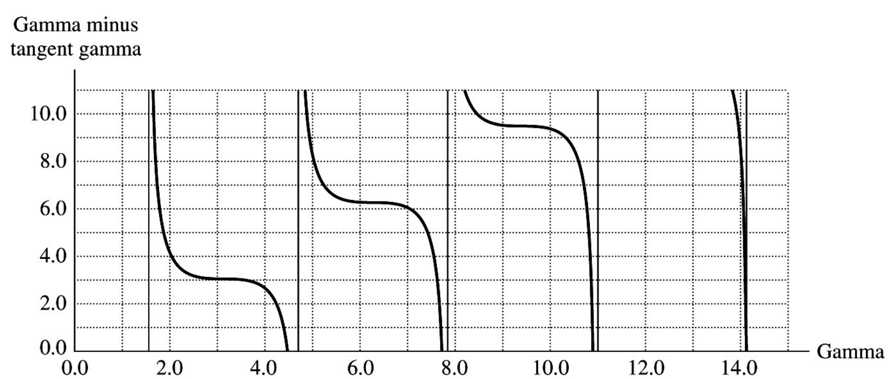

Figure 36.51

(c) The minima occur when $\gamma = \pm m\pi$, where $m = 1, 2, 3, \ldots$, so the first three positive ones are $\gamma = \pi$, 2π, and 3π. From part (b), the first maximum is at $\gamma = 4.49$ rad. Midway between the first and second minima is $\gamma = \pi + \pi/2 = 3\pi/2 = 4.71$ rad. Clearly 4.49 rad $\neq$ 4.71 rad, so this maximum is not midway between the adjacent minima. The second maximum is at $\gamma = 7.73$ rad. Midway between the second and third minima is $\gamma = 2\pi + \pi/2 = 5\pi/2 = 7.85$ rad. Since $7.73 \neq 7.85$, the second maximum is not midway between the adjacent minima.

(d) Using $a = 12\,\lambda$, we have $\gamma = \dfrac{\pi a\sin\theta}{\lambda} = \dfrac{\pi(12\lambda)\sin\theta}{\lambda} = 12\pi\sin\theta$. Using this we get the following:

First minimum: $\gamma = \pi$, so $\pi = 12\pi\sin\theta \quad \rightarrow \quad \theta = 4.78°$.

First maximum: $\gamma = 2\pi$, so $2\pi = 12\pi\sin\theta \quad \rightarrow \quad \theta = 6.84°$.

Second minimum: $\gamma = 3\pi$, so $3\pi = 12\pi\sin\theta \quad \rightarrow \quad \theta = 9.59°$.

Midway between these minima is $\theta = (9.59° + 4.78°)/2 = 7.19°$. The first maximum is at $\theta = 6.84°$, and since $6.84° \neq 7.19°$, the first minimum is *not* midway between the adjacent minima.

EVALUATE: $\gamma = 0$ is the central maximum. The three values of γ we found are the locations of the first two secondary maxima. The first three minima are at $\gamma = 3.14$ rad, 6.28 rad, and 9.42 rad. The maxima are between adjacent minima, but not precisely midway between them.

36.52. **(a) IDENTIFY** and **SET UP:** The angular position of the first minimum is given by $a\sin\theta = m\lambda$, with $m = 1$. The distance of the minimum from the center of the pattern is given by $y = x\tan\theta$.

EXECUTE: $\sin\theta = \dfrac{\lambda}{a} = \dfrac{540\times10^{-9}\text{ m}}{0.360\times10^{-3}\text{ m}} = 1.50\times10^{-3}$; $\theta = 1.50\times10^{-3}$ rad.

$y_1 = x\tan\theta = (1.20\text{ m})\tan(1.50\times10^{-3}\text{ rad}) = 1.80\times10^{-3}\text{ m} = 1.80\text{ mm}.$

(Note that θ is small enough for $\theta \approx \sin\theta \approx \tan\theta$, and $y_m = x\dfrac{m\lambda}{a}$ applies.)

(b) IDENTIFY and **SET UP:** Find the phase angle β where $I = I_0/2$. Then use $\beta = \left(\dfrac{2\pi}{\lambda}\right)a\sin\theta$ to solve for θ and $y = x\tan\theta$ to find the distance.

EXECUTE: $I = I_0\left(\dfrac{\sin\beta/2}{\beta/2}\right)^2$ gives that $I = \tfrac{1}{2}I_0$ when $\beta = 2.78$ rad.

$\beta = \left(\dfrac{2\pi}{\lambda}\right)a\sin\theta$, so $\sin\theta = \dfrac{\beta\lambda}{2\pi a}$.

$$y = x\tan\theta \approx x\sin\theta \approx \frac{\beta\lambda x}{2\pi a} = \frac{(2.78\text{ rad})(540\times10^{-9}\text{ m})(1.20\text{ m})}{2\pi(0.360\times10^{-3}\text{ m})} = 7.96\times10^{-4}\text{ m} = 0.796\text{ mm}.$$

EVALUATE: The point where $I = I_0/2$ is not midway between the center of the central maximum and the first minimum.

36.53. **IDENTIFY:** Heating the plate causes it to expand, which widens the slit. The increased slit width changes the angles at which destructive interference occurs.

SET UP: First minimum is at angle θ given by $\tan\theta = \dfrac{(2.75\times10^{-3}/2)}{0.620}$. Therefore, θ is small and the equation $y_m = x\dfrac{m\lambda}{a}$ is accurate. The width of the central maximum is $w = \dfrac{2x\lambda}{a}$. The change in slit width is $\Delta a = a\alpha\Delta T$.

EXECUTE: $dw = 2x\lambda\left(-\dfrac{da}{a^2}\right) = -\dfrac{2x\lambda}{a^2}da = -\dfrac{w}{a}da$. Therefore, $\Delta w = -\dfrac{w}{a}\Delta a$. The equation for thermal expansion says $\Delta a = a\alpha\Delta T$, so $\Delta w = -w\alpha\Delta T = -(2.75\text{ mm})(2.4\times10^{-5}\text{ K}^{-1})(500\text{ K}) = -0.033\text{ mm}$.

When the temperature of the plate increases, the width of the slit increases and the width of the central maximum decreases.

EVALUATE: The fractional change in the width of the central maximum is $\dfrac{0.033\text{ mm}}{2.75\text{ mm}} = 1.2\%$. This is small, but observable.

36.54. **IDENTIFY:** The wavelength of the helium spectral line from the receding galaxy will be different from the spectral line on earth due to the Doppler shift in the light from the galaxy.

SET UP: $d\sin\theta = m\lambda$. $\sin\theta_{\text{lab}} = \dfrac{2\lambda_{\text{lab}}}{d}$. $\sin\theta_{\text{galaxy}} = \dfrac{2\lambda_{\text{galaxy}}}{d}$. $\sin\theta_{\text{galaxy}} = \sin\theta_{\text{lab}}\left(\dfrac{\lambda_{\text{lab}}}{\lambda_{\text{galaxy}}}\right)$. The Doppler formula says $f_{\text{R}} = \sqrt{\dfrac{c-v}{c+v}}f_{\text{S}}$. Using $f = \dfrac{c}{\lambda}$, we have $\dfrac{1}{\lambda_{\text{R}}} = \dfrac{1}{\lambda_{\text{S}}}\sqrt{\dfrac{c-v}{c+v}}$. Since the lab is the receiver R and the galaxy is the source S, this becomes $\lambda_{\text{lab}} = \lambda_{\text{galaxy}}\sqrt{\dfrac{c+v}{c-v}}$.

EXECUTE: $\sin\theta_{\text{galaxy}} = \sin\theta_{\text{lab}}\sqrt{\dfrac{c+v}{c-v}} = \sin(18.9^\circ)\sqrt{\dfrac{2.998\times10^8\ \text{m/s} + 2.65\times10^7\ \text{m/s}}{2.998\times10^8\ \text{m/s} - 2.65\times10^7\ \text{m/s}}}$ which gives $\theta_{\text{galaxy}} = 20.7^\circ$.

EVALUATE: The galaxy is moving away, so the wavelength of its light will be lengthened, which means that the angle should be increased compared to the angle from light on earth, as we have found.

36.55. **IDENTIFY** and **SET UP:** The condition for an intensity maximum is $d\sin\theta = m\lambda$, $m = 0, \pm1, \pm2, \ldots$. Third order means $m = 3$. The longest observable wavelength is the one that gives $\theta = 90^\circ$ and hence $\sin\theta = 1$.

EXECUTE: 9200 lines/cm so 9.2×10^5 lines/m and $d = \dfrac{1}{9.2\times10^5}\ \text{m} = 1.087\times10^{-6}\ \text{m}$.

$$\lambda = \frac{d\sin\theta}{m} = \frac{(1.087\times10^{-6}\ \text{m})(1)}{3} = 3.6\times10^{-7}\ \text{m} = 360\ \text{nm}.$$

EVALUATE: The longest wavelength that can be obtained decreases as the order increases.

36.56. **IDENTIFY:** We are dealing with single-slit diffraction for sound waves.
SET UP and **EXECUTE:** **(a)** Estimate: Door width = 75 cm.
(b) We want *f*. $f = v/\lambda$ = (344 m/s)/(0.75 m) = 460 Hz.

(c) We want *f* for diffraction at ±20°. $a\sin\theta = \lambda = v/f$, so $f = \dfrac{v}{a\sin\theta} = \dfrac{344\ \text{m/s}}{(0.75\ \text{m})\sin 20^\circ} = 1.3\ \text{kHz}$.

(d) It is fairly good. A frequency of 1.3 kHz is typical of many ordinary sounds and much music, so not very much sound would bend around the edge of a doorway.
(e) Since $a\sin\theta = \lambda$, a small wavelength would undergo less bending, so higher frequency sounds would bend less than lower frequency sounds.
EVALUATE: **(f)** It is somewhat observable. Inside the house there are reflections from nearby walls. Outside has more open space with fewer reflections.

36.57. **IDENTIFY:** The maxima are given by $d\sin\theta = m\lambda$. We need $\sin\theta = \dfrac{m\lambda}{d} \le 1$ in order for all the visible wavelengths to be seen.

SET UP: For 650 slits/mm $\Rightarrow d = \dfrac{1}{6.50\times10^5\ \text{m}^{-1}} = 1.53\times10^{-6}\ \text{m}$. The visible spectrum is approximately between 380 nm and 750 nm.

EXECUTE: $\lambda_1 = 3.8\times10^{-7}\text{m}$: $m = 1$: $\dfrac{\lambda_1}{d} = 0.247$; $m = 2$: $\dfrac{2\lambda_1}{d} = 0.494$; $m = 3$: $\dfrac{3\lambda_1}{d} = 0.741$.

$\lambda_2 = 7.5\times10^{-7}\text{m}$: $m = 1$: $\dfrac{\lambda_2}{d} = 0.4875$; $m = 2$: $\dfrac{2\lambda_2}{d} = 0.975$; $m = 3$: $\dfrac{3\lambda_2}{d} = 1.46$. So, the third order does not contain the violet end of the spectrum, and therefore only the first- and second-order diffraction patterns contain all colors of the spectrum.

EVALUATE: θ for each maximum is larger for longer wavelengths.

36.58. **IDENTIFY:** Apply $\sin\theta = 1.22\dfrac{\lambda}{D}$.

SET UP: θ is small, so $\sin\theta \approx \dfrac{\Delta x}{R}$, where Δx is the size of the detail and $R = 7.2\times10^{8}$ ly.

$1\text{ ly} = 9.41\times10^{12}$ km. $\lambda = c/f$.

EXECUTE:

$$\sin\theta = 1.22\frac{\lambda}{D} \approx \frac{\Delta x}{R} \Rightarrow \Delta x = \frac{1.22\lambda R}{D} = \frac{(1.22)cR}{Df} = \frac{(1.22)(3.00\times10^{5}\text{ km/s})(7.2\times10^{8}\text{ ly})}{(77.000\times10^{3}\text{ km})(1.665\times10^{9}\text{ Hz})} = 2.06\text{ ly}.$$

$(9.41\times10^{12}\text{ km/ly})(2.06\text{ ly}) = 1.94\times10^{13}$ km.

EVALUATE: $\lambda = 18$ cm. λ/D is very small, so $\dfrac{\Delta x}{R}$ is very small. Still, R is very large and Δx is many orders of magnitude larger than the diameter of the sun.

36.59. **IDENTIFY:** This problem is about x-ray diffraction applied to electrons.

SET UP: Eq. (36.16): $2d\sin\theta_m = m\lambda$ for constructive interference.

EXECUTE: **(a)** Using Fig. 36.22a in the textbook, we see that $2\theta + 50° = 180°$, so $\theta = 65°$.

(b) We want λ for electrons. $2d\sin\theta = \lambda$ = 2(0.091 nm)(sin 65°) = 0.16 nm.

(c) We want the electron speed. $K = \dfrac{1}{2}mv^2$ = 54 eV = 8.64×10^{-18} J. $v = \sqrt{2K/m}$. Using our K gives $v = 4.4\times10^{6}$ m/s.

(d) We want the frequency of the electron. $f = v/\lambda$. Using the results of (b) and (c), we have $f = 2.6\times10^{16}$ Hz.

(e) We want h. $E = hf$ gives $h = E/f$. Using E from part (c) and f from part (d) gives $h = 3.3\times10^{-34}\text{ J}\cdot\text{s}$.

(f) We want h. $v = \dfrac{1}{2}v_{\text{cl}}$, so $f = \dfrac{\frac{1}{2}v_{\text{cl}}}{\lambda}$. Thus $h = \dfrac{E}{f} = \dfrac{E}{\frac{1}{2}v_{\text{cl}}} = 2\dfrac{E}{v_{\text{cl}}/\lambda} = 2(3.3\times10^{-34}\text{ J}\cdot\text{s}) =$ $6.6\times10^{-34}\text{ J}\cdot\text{s}$.

EVALUATE: **(g)** The established value is $h = 6.6\times10^{-34}\text{ J}\cdot\text{s}$ so our result agrees well.

36.60. **IDENTIFY:** The resolution of the eye is limited because light diffracts as it passes through the pupil. The size of the pupil determines the resolution.

SET UP: The smallest angular separation that can be resolved is $\theta_{\text{res}} = 1.22\dfrac{\lambda}{D}$. The angular size of the object is its height divided by its distance from the eye.

EXECUTE: **(a)** The angular size of the object is $\theta = \dfrac{50\times10^{-6}\text{ m}}{25\times10^{-2}\text{ m}} = 2.0\times10^{-4}$ rad.

$\theta_{\text{res}} = 1.22\dfrac{\lambda}{D} = 1.22\left(\dfrac{550\times10^{-9}\text{ m}}{2.0\times10^{-3}\text{ m}}\right) = 3.4\times10^{-4}$ rad. $\theta < \theta_{\text{res}}$ so the object cannot be resolved.

(b) $\theta_{\text{res}} = \dfrac{y}{s}$ and $y = s\theta_{\text{res}} = (25\text{ cm})(3.4\times10^{-4}\text{ rad}) = 8.5\times10^{-3}\text{ cm} = 85\ \mu\text{m}$.

(c) $\theta = \theta_{\text{res}} = 3.4\times10^{-4}\text{ rad} = 0.019° = 1.1\text{ min}$. This is very close to the experimental value of 1 min.

(d) Diffraction is more important.

EVALUATE: We could not see any clearer if our retinal cells were much smaller than they are now because diffraction is more important in limiting the resolution of our vision.

36.61. **IDENTIFY:** A double-slit bright fringe is missing when it occurs at the same angle as a double-slit dark fringe.

SET UP: Single-slit diffraction dark fringes occur when $a\sin\theta = m\lambda$, and double-slit interference bright
fringes occur when $d\ \sin\theta = m'\lambda$.

EXECUTE: **(a)** The angle at which the first bright fringe occurs is given by
$\tan\theta_1 = (1.53\text{ mm})/(2500\text{ mm}) \Rightarrow \theta_1 = 0.03507°$. $d\sin\theta_1 = \lambda$ and
$d = \lambda/(\sin\theta_1) = (632.8\text{ nm})/\sin(0.03507°) = 0.00103\text{ m} = 1.03\text{ mm}$.

(b) The 7^{th} double-slit interference bright fringe is just cancelled by the 1^{st} diffraction dark fringe, so $\sin\theta_{\text{diff}} = \lambda/a$ and $\sin\theta_{\text{interf}} = 7\lambda/d$.
The angles are equal, so $\lambda/a = 7\lambda/d \to a = d/7 = (1.03\text{ mm})/7 = 0.148\text{ mm}$.

EVALUATE: We can generalize that if $d = na$, where n is a positive integer, then every n^{th} double-slit bright fringe will be missing in the pattern.

36.62. **IDENTIFY:** Light from the slit produces a diffraction pattern on the screen.

SET UP: The first dark fringe occurs when $a\ \sin\ \theta_1 = \lambda$, and $\tan\theta_1 = (w/2)/R = w/2R$, where R is the distance from the slit to the screen.

EXECUTE: **(a)** If θ_1 is small, we can use the small-angle approximation $\sin\theta_1 \approx \tan\theta_1 = w/2R$. In that case, $aw = 2R\lambda$, which is constant. But if θ_1 is large, we cannot use $\sin\theta_1 \approx \tan\theta_1$, and wa is not constant. Figure 36.62 shows the graph of aw versus a for the data in the problem, and its curvature for small a shows that wa is not constant for small values of a.

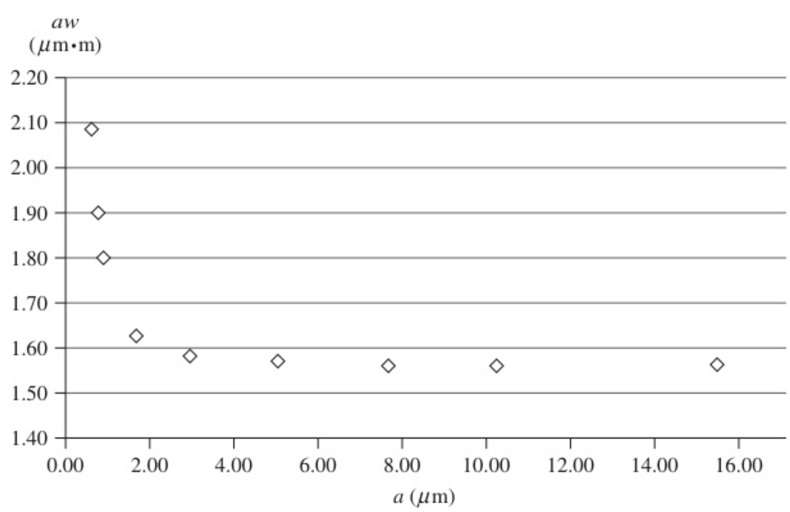

Figure 36.62

(b) We see that our graph flattens out for large values of a and $wa \to 1.56\times10^{-6}\text{ m}^2$. This means we can apply the small-angle approximation. In that case, $aw = 2R\lambda$, so
$\lambda = aw/2R = (1.56\times10^{-6}\text{ m}^2)/[2(1.50\text{ m})] = 5.20\times10^{-7}\text{ m} = 520\text{ nm}$.

(c) (i) Use $a\sin\theta_1 = \lambda$ with $a = 0.78\ \mu\text{m} = 780\text{ nm}$.

$(780\text{ nm})\sin\theta_1 = 520\text{ nm} \quad \to \quad \theta_1 = 42°$.

(ii) Now use $a = 15.60\ \mu\text{m} = 15{,}600\text{ nm}$.

$(15{,}600\text{ nm})\sin\theta_1 = 520\text{ nm} \quad \to \quad \theta_1 = 1.91°$.

EVALUATE: In part (c), we could use the small-angle approximation in (ii) but not in (i).

36.63. **IDENTIFY:** The hole produces a diffraction pattern on the screen.

SET UP: The first dark ring occurs when $D \sin\theta_1 = 1.22\,\lambda$, and $\tan\theta_1 = r/x$.

EXECUTE: **(a)** Solving for D gives $D = (1.22\,\lambda)/(\sin\theta_1)$. First use $\tan\theta_1 = r/x$ to find θ_1, and then calculate D.

First set: $\tan\theta_1 = r/x = (5.6 \text{ cm})/(100 \text{ cm}) \rightarrow \theta_1 = 3.205°$.

$D = (1.22)(562 \text{ nm})/[\sin(3.205°)] = 1.226 \times 10^4$ nm.

Second set: $\tan\theta_1 = r/x = (8.5 \text{ cm})/(150 \text{ cm}) \rightarrow \theta_1 = 3.2433°$.

$D = (1.22)(562 \text{ nm})/[\sin(3.2433°)] = 1.212 \times 10^4$ nm.

Third set: $\tan\theta_1 = r/x = (11.6 \text{ cm})/(200 \text{ cm}) \rightarrow \theta_1 = 3.3194°$.

$D = (1.22)(562 \text{ nm})/[\sin(3.3194°)] = 1.184 \times 10^4$ nm.

Fourth set: $\tan\theta_1 = r/x = (14.1 \text{ cm})/(250 \text{ cm}) \rightarrow \theta_1 = 3.2281°$.

$D = (1.22)(562 \text{ nm})/[\sin(3.2281°)] = 1.218 \times 10^4$ nm.

Taking the average gives

$D_{av} = [(1.226 + 1.212 + 1.184 + 1.218) \times 10^4 \text{ nm}]/4 = 1.21 \times 10^4 \text{ nm} = 12.1\ \mu\text{m}$.

(b) $\sin\theta_2 = 2.23\,\lambda/D = (2.23)(562 \text{ nm})/(1.21 \times 10^4 \text{ nm}) \rightarrow \theta_2 = 5.945°$.

$r_2 = x_2 \tan\theta_2 = (1.00 \text{ m})\tan(5.945°) = 0.104 \text{ m} = 10.4$ cm.

$\sin\theta_3 = 3.24\,\lambda/D = (3.24)(562 \text{ nm})/(1.21 \times 10^4 \text{ nm}) \rightarrow \theta_3 = 8.6551°$.

$r_3 = x_3 \tan\theta_3 = (1.00 \text{ m})\tan(8.6551°) = 0.152 \text{ m} = 15.2$ cm.

EVALUATE: This is a very small hole, but its diameter is still over 20 times the wavelength of the light passing through it.

36.64. **IDENTIFY:** The liquid reduces the wavlength of the light (compared to its value in air), and the scratch causes light passing through it to undergo single-slit diffraction.

SET UP: $\sin\theta = \dfrac{\lambda}{a}$, where λ is the wavelength in the liquid. $n = \dfrac{\lambda_{\text{air}}}{\lambda}$.

EXECUTE: $\tan\theta = \dfrac{(22.4/2) \text{ cm}}{30.0 \text{ cm}}$ and $\theta = 20.47°$.

$\lambda = a\sin\theta = (1.25\times10^{-6} \text{ m})\sin 20.47° = 4.372\times10^{-7} \text{ m} = 437.2 \text{ nm}$. $n = \dfrac{\lambda_{\text{air}}}{\lambda} = \dfrac{612 \text{ nm}}{437.2 \text{ nm}} = 1.40$.

EVALUATE: $n > 1$, as it must be, and $n = 1.40$ is reasonable for many transparent films.

36.65. **IDENTIFY:** This problem involves single slit-diffraction and double-slit interference. As the membranes move along, the thickness of the slits varies because the membranes overlap. So we are dealing with a double slit having a variable slit width.

SET UP: For single-slit dark spots, $a\sin\theta_m = m\lambda\ (m = \pm1, \pm2, \cdots)$ and for double-slit bright spots $d\sin\theta_m = m\lambda\ (m = 0, \pm1, \pm2, \cdots)$.

EXECUTE: **(a)** We want the slit spacing d. At t = 1.00 s the edges of the screen are totally dark but the rest of the screen contains a series of 19 spots of nearly equal brightness. These are the double-slit interference spots. There is one in the middle of the screen and 9 on each side of the center. The spots that would be at the edges of the screen are missing, and they are the $m = \pm10$ spots. Therefore $\theta_{10} = \pm30.0°$ from the center. For double-slit bright spots, we have $d\sin\theta_{10} = 10\lambda$. Solving for d gives

$$d = \frac{10\lambda}{\sin\theta_{10}} = \frac{10(532 \text{ nm})}{\sin(30.0°)} = 10.6\ \mu\text{m}.$$

(b) We want the speed v of the membranes. The width of the slits at 1.00 s is given by $a_1\sin\theta_1 = \lambda$. We use m = 1 because this is the first single-slit dark spot. This dark spot occurs at the angle for which the m = 10 double-slit bright spot would have occurred, so $\theta_1 = 30°$. Solving for a_1 gives

$a_1 = \dfrac{\lambda}{\sin\theta_{10}} = \dfrac{532 \text{ nm}}{\sin(30.0°)} = 1064 \text{nm}$. The slit width increased from 0 nm to 1064 nm in 1.00 s. The membranes move with equal speed in opposite directions, so each one traveled half this distance in that time. Therefore $vt_1 = a/2$, which gives $v = a_1/2t_1$ = (1064 nm)/[2(1.00 s)] = 532 nm/s.

(c) We want the maximum slit width a. At $t = 0$ the slits are closed and at $t = 3.00$ s they are closed again. So at $t = 1.50$ s they reach their maximum width. During this time each membrane travels a distance of $a/2$. Thus $vt = a/2$, which gives $a = 2vt = 2(532 \text{ nm/s})(1.50 \text{ s}) = 1.60\ \mu\text{m}$.

(d) We want the time at which the $m = \pm 9$ spots suddenly disappear. The slits are now thicker than they were at $t = 1.00$ s so the $m = 1$ single-slit dark spot has moved closer to the center and now cancels the $m = \pm 9$ double-slit bright spots. To find this slit width a_2, consider the double-slit pattern. The $m = 9$ bright spot would be at θ_9 which is given by $d\sin\theta_9 = 9\lambda$. From this we get

$\sin\theta_9 = \dfrac{9\lambda}{d} = \dfrac{9(532 \text{ nm})}{10.6\,\mu\text{m}} = 0.4517$. θ_9 is now the angle of the first single-slit dark spot, so $a_2 \sin\theta_9 = \lambda$, which gives $a_2 = \dfrac{\lambda}{\sin\theta_9} = \dfrac{532 \text{ nm}}{0.4517} = 1178 \text{nm}$. The slit width started at 0 at $t = 0$ and is now equal to 1178 nm. As in part (b), $vt_2 = a_2/2$, so $t_2 = a_2/2v$ = (1178 nm)/[2(532 nm/s)] = 1.11 s.

(e) We want the intensity I at the first double-slit bright spot. At 1.50 s the slits are at their maximum width of 1.60 μm. The intensity is $I = I_0\cos^2(\phi/2)\left[\dfrac{\sin(\beta/2)}{\beta/2}\right]^2$. At the first bright spot $\cos(\phi/2) = 1$ and $d\sin\theta = \lambda$, so $\sin\theta = \lambda/d$. Using this to find $\beta/2$ gives

$\beta/2 = \dfrac{\pi a\sin\theta}{\lambda} = \dfrac{\pi a(\lambda/d)}{\lambda} = \dfrac{\pi a}{d} = \dfrac{\pi(1.60\,\mu\text{m})}{10.6\,\mu\text{m}} = 0.4742 \text{ rad} = 27.17°$. The intensity is

$I = I_0\left[\dfrac{\sin(27.19°)}{0.4742 \text{ rad}}\right]^2 = 0.927 I_0 = 92.7\%$ of I_0.

(f) We want the angle at which the first double-slit bright spot occurs. This is the first such spot, so $d\sin\theta = \lambda/d$ = (532 nm)/(10.6 μm) = 0.0519, so θ = 2.88°.

EVALUATE: A device like this would make an interesting demonstration in a physics lecture or at a science fair.

36.66. **IDENTIFY** and **SET UP:** Follow the steps specified in the problem.

EXECUTE: **(a)** Each source can be thought of as a traveling wave evaluated at $x = R$ with a maximum amplitude of E_0. However, each successive source will pick up an extra phase from its respective pathlength to point P. $\phi = 2\pi\left(\dfrac{d \sin\theta}{\lambda}\right)$ which is just 2π, the maximum phase, scaled by whatever fraction the path difference, $d \sin\theta$, is of the wavelength, λ. By adding up the contributions from each source (including the accumulating phase difference) this gives the expression provided.

(b) $e^{i(kR-\omega t+n\phi)} = \cos(kR-\omega t+n\phi) + i\sin(kR-\omega t+n\phi)$. The real part is just $\cos(kR-\omega t+n\phi)$. So, $\text{Re}\left[\sum\limits_{n=0}^{N-1} E_0 e^{i(kR-\omega x+n\phi)}\right] = \sum\limits_{n=0}^{N-1} E_0\cos(kR-\omega x+n\phi)$. (Note: Re means "the real part of…."). But this is just $E_0\cos(kR-\omega t) + E_0\cos(kR-\omega t+\phi) + E_0\cos(kR-\omega t+2\phi) + \cdots + E_0\cos(kR-\omega t+(N-1)\phi)$.

(c) $\sum\limits_{n=0}^{N-1} E_0\, e^{i(kR-\omega t+n\phi)} = E_0 \sum\limits_{n=0}^{N-1} e^{-i\omega t}\, e^{+ikR} e^{in\phi} = E_0 e^{i(kR-\omega t)} \sum\limits_{n=0}^{N-1} e^{in\phi}$. $\sum\limits_{n=0}^{\infty} e^{in\phi} = \sum\limits_{n=0}^{N-1} (e^{i\phi})^n$. But recall $\sum\limits_{n=0}^{N-1} x^n = \dfrac{x^N - 1}{x-1}$. Putting everything together:

$$\sum_{n=0}^{N-1} E_0 e^{i(kR-\omega t+n\phi)} = E_0 e^{i(kR-\omega t+(N-1)\phi/2)} \frac{(e^{iN\phi/2} - e^{-iN\phi/2})}{(e^{i\phi/2} - e^{-i\phi/2})}$$

$$= E_0[\cos(kR - \omega t + (N-1)\phi/2) + i\sin(kR - \omega t + (N-1)\phi/2)]\left[\frac{\cos N\phi/2 + \sin N\phi/2 - \cos N\phi/2 + i\sin N\phi/2}{\cos\phi/2 + i\sin\phi/2 - \cos\phi/2 + i\sin\phi/2}\right].$$

Taking only the real part gives $\Rightarrow E_0\cos(kR - \omega t + (N-1)\phi/2)\dfrac{\sin(N\phi/2)}{\sin\phi/2} = E.$

(d) $I = |E|^2_{\text{av}} = I_0\dfrac{\sin^2(N\phi/2)}{\sin^2(\phi/2)}$. (The $\cos^2$ term goes to $\frac{1}{2}$ in the time average and is included in the definition of I_0.) $I_0 \propto \dfrac{E_0^2}{2}$.

EVALUATE: **(e)** $N = 2$. $I = I_0\dfrac{\sin^2(2\phi/2)}{\sin^2\phi/2} = \dfrac{I_0(2\sin\phi/2\cos\phi/2)^2}{\sin^2\phi/2} = 4I_0\cos^2\dfrac{\phi}{2}$. Looking at Eq. (35.9), $I'_0 \propto 2E_0^2$ but for us $I_0 \propto \dfrac{E_0^2}{2} = \dfrac{I'_0}{4}$.

36.67. **IDENTIFY** and **SET UP:** From Problem 36.66, $I = I_0\dfrac{\sin^2(N\phi/2)}{\sin^2\phi/2}$. Use this result to obtain each result specified in the problem.

EXECUTE: **(a)** $\lim\limits_{\phi\to 0} I \to \dfrac{0}{0}$. Use 1'Hôpital's rule: $\lim\limits_{\phi\to 0}\dfrac{\sin(N\phi/2)}{\sin\phi/2} = \lim\limits_{\phi\to 0}\left(\dfrac{N/2}{1/2}\right)\dfrac{\cos(N\phi/2)}{\cos(\phi/2)} = N$. So $\lim\limits_{\phi\to 0} I = N^2 I_0$.

(b) The location of the first minimum is when the numerator first goes to zero at $\dfrac{N}{2}\phi_{\text{min}} = \pi$ or $\phi_{\text{min}} = \dfrac{2\pi}{N}$. The width of the central maximum goes like $2\phi_{\text{min}}$, so it is proportional to $\dfrac{1}{N}$.

(c) Whenever $\dfrac{N\phi}{2} = n\pi$ where n is an integer, the numerator goes to zero, giving a minimum in intensity. That is, I is a minimum wherever $\phi = \dfrac{2n\pi}{N}$. This is true assuming that the denominator doesn't go to zero as well, which occurs when $\dfrac{\phi}{2} = m\pi$, where m is an integer. When both go to zero, using the result from part(a), there is a maximum. That is, if $\dfrac{n}{N}$ is an integer, there will be a maximum.

(d) From part (c), if $\dfrac{n}{N}$ is an integer we get a maximum. Thus, there will be $N-1$ minima. (Places where $\dfrac{n}{N}$ is not an integer for fixed N and integer n.) For example, $n = 0$ will be a maximum, but $n = 1, 2\ldots, N-1$ will be minima with another maximum at $n = N$.

(e) Between maxima $\dfrac{\phi}{2}$ is a half-integer multiple of $\pi\left(\text{i.e.,}\dfrac{\pi}{2},\dfrac{3\pi}{2}\text{etc.}\right)$ and if N is odd then $\dfrac{\sin^2(N\phi/2)}{\sin^2\phi/2} \to 1$, so $I \to I_0$.

EVALUATE: These results show that the principal maxima become sharper as the number of slits is increased.

36.68. IDENTIFY and SET UP: Follow the steps specified in the problem.

EXECUTE: **(a)** From the segment dy', the fraction of the amplitude of E_0 that gets through is

$E_0\left(\frac{dy'}{a}\right) \Rightarrow dE = E_0\left(\frac{dy'}{a}\right)\sin(kx-\omega t).$

(b) The path difference between each little piece is

$y'\sin\theta \Rightarrow kx = k(D-y'\sin\theta) \Rightarrow dE = \frac{E_0 dy'}{a}\sin(k(D-y'\sin\theta)-\omega t).$ This can be rewritten as

$dE = \frac{E_0 dy'}{a}(\sin(kD-\omega t)\cos(ky'\sin\theta)+\sin(ky'\sin\theta)\cos(kD-\omega t)).$

(c) So the total amplitude is given by the integral over the slit of the above.

$\Rightarrow E = \int_{-a/2}^{a/2} dE = \frac{E_0}{a}\int_{-a/2}^{a/2} dy'\,(\sin(kD-\omega t)\cos(ky'\sin\theta)+\sin(ky'\sin\theta)\cos(kD-\omega t)).$

But the second term integrates to zero, so we have:

$E = \frac{E_0}{a}\sin(kD-\omega t)\int_{-a/2}^{a/2} dy'(\cos(ky'\sin\theta)) = E_0\sin(kD-\omega t)\left[\left(\frac{\sin(ky'\sin\theta)}{ka\sin\theta/2}\right)\right]_{-a/2}^{a/2}$

$\Rightarrow E = E_0\sin(kD-\omega x)\left(\frac{\sin(ka(\sin\theta)/2)}{ka(\sin\theta)/2}\right) = E_0\sin(kD-\omega x)\left(\frac{\sin(\pi a(\sin\theta)/\lambda)}{\pi a(\sin\theta)/\lambda}\right).$

At $\theta = 0, \frac{\sin[\ldots]}{[\ldots]} = 1 \Rightarrow E = E_0\sin(kD-\omega x).$

(d) Since $I \propto E^2 \Rightarrow I = I_0\left(\frac{\sin(ka(\sin\theta)/2)}{ka(\sin\theta)/2}\right)^2 = I_0\left(\frac{\sin(\beta/2)}{\beta/2}\right)^2$, where we have used

$I_0 = E_0^2\sin^2(kx-\omega t).$

EVALUATE: The same result for $I(\theta)$ is obtained as was obtained using phasors.

36.69. IDENTIFY and SET UP: For an interference maxima, $2d\sin\theta = m\lambda_0/n.$ The microspheres are in water, so we use n = 1.3. Do a rough calculation to estimate the distance between microspheres.

EXECUTE: Use the numbers in the problem and $n = 1.3.$ Solving $2d\sin\theta = m\lambda_0/n$ for d gives

$d = \frac{m\lambda_0}{2n\sin\theta} = \frac{(1)(650\text{ nm})}{2(1.3)\sin 39°} \approx 400$ nm. This distance is much greater than the spacing of atoms in a crystal and is comparable to the wavelength of visible light. Therefore choice (d) is correct.

EVALUATE: The atoms in a crystal are tightly bound by the electric force between them and are therefore very close together.

36.70. IDENTIFY and SET UP: For an interference maxima, $2d\sin\theta = m\lambda_0/n.$ The microspheres are in water, so we use n = 1.33.

EXECUTE: $d = \frac{m\lambda_0}{2n\sin\theta} = \frac{(1)(650\text{ nm})}{2(1.33)\sin 39°} \approx 390$ nm. Choice (a) is the correct one.

EVALUATE: We are assuming that the microspheres do not affect the index of refraction of the water.

36.71. IDENTIFY and SET UP: For an interference maxima, $2d\sin\theta = m\lambda_0/n,$ so $\sin\theta \propto \frac{1}{d}.$ If d is smaller, $\sin\theta,$ and hence $\theta,$ is larger.

EXECUTE: At the top $\theta_{\text{top}} = 37°$, and at the bottom $\theta_{\text{bottom}} = 41°.$ Since $\theta_{\text{top}} < \theta_{\text{bottom}}, <$ it follows that $d_{\text{top}} > d_{\text{bottom}}$. Therefore the microspheres are closer together at the bottom than at the top, which makes choice (a) the correct one.

EVALUATE: Gravity tends to pull the spheres downward so they bunch up at the bottom, making them closer together.

37

RELATIVITY

VP37.5.1. **IDENTIFY:** This problem is about time dilation.

SET UP: $\Delta t = \dfrac{\Delta t_0}{\sqrt{1-u^2/c^2}}$. We want the mean lifetime of the K^+ particle.

EXECUTE: **(a)** At $u = 0.800c$: $\Delta t = \dfrac{1.23\times10^{-8}\text{ s}}{\sqrt{1-(0.800)^2}} = 2.05\times10^{-8}\text{ s}.$

(b) At $u = 0.800\,c$: To the first K^+, the second one is moving at $u = 0.800c$, so the answer is the same as in part (a): $\Delta t = 2.05\times10^{-8}$ s.

EVALUATE: The relative speed of the K^+ is the same in both cases, so the lifetime is the same.

VP37.5.2. **IDENTIFY:** This problem is about time dilation.

SET UP: $\Delta t = \dfrac{\Delta t_0}{\sqrt{1-u^2/c^2}}$. We want the time interval that both Paul and Alia read.

EXECUTE: **(a)** Paul's timer reads the proper time, so solve for Δt_0.

$\Delta t_0 = \Delta t\sqrt{1-u^2/c^2} = (20.0\text{ s})\sqrt{1-(0.600)^2} = 16.0\text{ s}.$

(b) Alia's time is the proper time. $\Delta t = \dfrac{24.0\text{ s}}{\sqrt{1-(0.600)^2}} = 30.0\text{ s}.$

EVALUATE: The proper time is the time measured by the observer at rest in her frame.

VP37.5.3. **IDENTIFY:** This problem is about length contraction.

SET UP: $L = L_0\sqrt{1-u^2/c^2}$. We want the distances and times measured.

EXECUTE: **(a)** In your frame, the proper length is 1.50×10^{11} m. $\Delta t = d/u = (1.50\times10^{11}\text{ m})/(0.950c)$ $= 526$ s.

(b) For the astronaut, the distance is length contracted.

$L == (1.50\times10^{11}\text{ m})\sqrt{1-(0.950)^2} = 4.68\times10^{10}\text{ m}.$ For the astronaut, the sun is moving toward him at $0.950c$, so $\Delta t = L/u = (4.68\times10^{10}\text{ m})/(0.950c) = 164$ s.

EVALUATE: Check: Use time dilation. To a person on Earth, the trip takes 526 s. The proper time is the astronaut's time, so $\Delta t_E = \dfrac{\Delta t_A}{\sqrt{1-(0.950)^2}} = 526\text{ s}.$

VP37.5.4. **IDENTIFY:** This problem is about length contraction.

SET UP: $L = L_0\sqrt{1-u^2/c^2}$, $\Delta t = \dfrac{\Delta t_0}{\sqrt{1-u^2/c^2}}$. For you, it takes 6.00 s for the rocket clock to read 2.00 s. You measure $L_{\text{rocket}} = 24.0$ m. We want the distances measured by the astronaut in the spacecraft.

EXECUTE: **(a)** Earth-Moon distance: First find the spacecraft's speed relative to Earth. The proper time is 2.00 s in the rocket. $6.00\text{ s} = \dfrac{2.00\text{ s}}{\sqrt{1-u^2/c^2}}$, so $\sqrt{1-u^2/c^2} = 0.333$. To the astronaut, the Earth-Moon distance is length-contracted. $L = L_0\sqrt{1-u^2/c^2} = (3.84\times10^5\text{ km})(0.333) = 1.28\times10^5\text{ km}$.

(b) The proper length of the spacecraft is measured by the astronaut, so $L_0 = \dfrac{L}{\sqrt{1-u^2/c^2}} = \dfrac{24.0\text{ m}}{0.333}$ $= 72.0$ m.

EVALUATE: The Earth observer sees the spacecraft length-contracted and the astronaut sees the Earth-Moon distance length-contracted.

VP37.7.1. **IDENTIFY:** This problem is about the Lorentz transformation equations.

SET UP: $x' = \gamma(x-ut)$, $t' = \gamma\left(t - xu/c^2\right)$. $\gamma = \dfrac{1}{\sqrt{1-u^2/c^2}} = \dfrac{1}{\sqrt{1-(0.750)^2}} = 1.512$. Gamora is the primed frame and Nebula is the unprimed frame.

EXECUTE: **(a)** We want the coordinates as measured by Gamora. Using $x' = \gamma(x-ut)$, we have ut $= (0.750c)(2.50\text{ s}) = 5.625\times10^8$ m. $x' = (1.512)(0 - 5.625\times10^8\text{ m}) = 8.50\times10^8$ m. Using $t' = \gamma\left(t - xu/c^2\right)$ gives $t' = (1.512)(2.50\text{ s} - 0) = 3.78$ s.

(b) We want the coordinates as measured by Nebula. She is the unprimed frame, so $x = \gamma(x'+ut)$ and $t = \gamma\left(t' + x'u/c^2\right)$. $x'u/c^2 = (4.00\times10^8\text{ m})(0.750c)/c^2 = 1.00$ s. This gives $x = \gamma(x'+ut) =$ $(1.512)(4.00\times10^8\text{ m} + 5.625\times10^8\text{ m}) = 1.46\times10^9$ m. $t = \gamma\left(t' + x'u/c^2\right) = (1.512)(2.50\text{ s} + 1.00\text{ s})$ $= 5.29$ s.

EVALUATE: Be very careful to decide which are the primed and unprimed frames.

VP37.7.2. **IDENTIFY:** This problem is about the Lorentz transformation equations.

SET UP: $x' = \gamma(x-ut)$, $t' = \gamma\left(t - xu/c^2\right)$. $\gamma = \dfrac{1}{\sqrt{1-u^2/c^2}} = \dfrac{1}{\sqrt{1-(0.800)^2}} = 1.6667$. Doreen is the primed frame and Kamala is the unprimed frame. In Kamala's frame, the events are simultaneous but occur at different places. In Doreen's frame the events are 0.600 s apart. We want the distance between the two events as measured by Doreen and Kamala.

EXECUTE: **(a)** In Kamala's frame: Use the Lorentz transformation equation for time and solve for Δx_K. $\Delta t'_D = \gamma\left(\Delta t_K - x_K u/c^2\right)$. $0.600\text{ s} = (1.6667)\left(0 - \Delta x_K(0.800c)/c^2\right)$. $\Delta x_K = 1.35\times10^8$ m.

(b) In Doreen's frame: $\Delta x'_D = \gamma(\Delta x_K - u\Delta t_K) = \Delta x'_D = \gamma(\Delta x_K - 0) = (1.6667)(1.35\times10^8\text{ m})$ $= 2.25\times10^8$ m.

EVALUATE: The distances are different because of their relative motion.

VP37.7.3. **IDENTIFY:** This problem is about relative velocity.

SET UP: $v'_x = \dfrac{v_x - u}{1 - uv_x/c^2}$, $v_x = \dfrac{v'_x + u}{1 + uv'_x/c^2}$. Fig. 37.7.3 shows the motions involved.

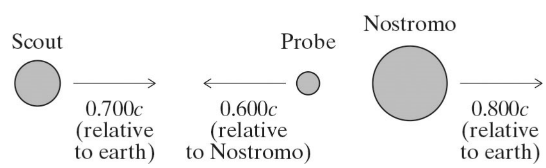

Figure VP37.7.3

EXECUTE: (a) We want the velocity of the probe relative to Earth. Let *Nostromo* be the primed frame moving relative to Earth at 0.800c in the +x direction. Earth is the unprimed frame.

$$v_x = \frac{v'_x + u}{1 + uv'_x/c^2} = \frac{-0.600c + 0.800c}{1 + (0.800c)(-0.600c)/c^2} = +0.385c.$$

(b) We want the velocity of the Scout ship relative to *Nostromo*. Let *Nostromo* be the primed frame and Earth the unprimed frame. We want v'_x. Using $v'_x = \frac{v_x - u}{1 - uv_x/c^2}$ gives

$$v'_x = \frac{0.700c - 0.800c}{1 - (0.800c)(0.700c)/c^2} = -0.227c.$$

EVALUATE: The result in (b) is reasonable because *Nostromo* is moving faster than the Scout probe, so relative to *Nostromo*, the Scout is moving in the –x direction.

VP37.7.4. IDENTIFY This problem is about relative velocity.

SET UP: $v'_x = \frac{v_x - u}{1 - uv_x/c^2}$. We want the speed of *Yamato* relative to *Macross.*

EXECUTE: (a) *Yamato* is flying toward Earth. Let *Macross* be the primed frame and Earth the unprimed frame. We want v'_Y. $v'_x = \frac{v_x - u}{1 - uv_x/c^2}$ becomes $v'_Y = \frac{v_Y - u}{1 - uv_Y/c^2}$

$$= \frac{-650c - 0.750c}{1 - (0.750c)(-0.650c)/c^2} = -0.941c.$$ *Yamato's* speed is 0.941c.

(b) *Yamato* is flying away from Earth. $v'_Y = \frac{+650c - 0.750c}{1 - (0.750c)(+0.650c)/c^2} = -0.195c.$

EVALUATE: In both cases *Yamato* has a negative velocity component because relative to *Macross*, *Yamato* is getting closer, hence moving in the –x direction. The relative speed in (b) is less than that in (a), as expected.

VP37.11.1. IDENTIFY: This problem deals with the force on a proton and its momentum at high speeds.

SET UP and EXECUTE: $\gamma = \frac{1}{\sqrt{1 - u^2/c^2}} = \frac{1}{\sqrt{1 - (0.950)^2}} = 3.20256.$ **(a)** We want the momentum.

$$p = m\gamma c = (1.67 \times 10^{-27}\ \text{kg})(3.20256)c = 1.52 \times 10^{-18}\ \text{kg} \cdot \text{m/s}.$$

(b) We want the acceleration. If the force and velocity are along the same line, $F = \gamma^3 ma$. So $a = \frac{F}{m\gamma^3}$.

Using the given numbers gives $a = 1.64 \times 10^{12}\ \text{m/s}^2$.

(c) We want the acceleration. If the force and velocity are perpendicular, $F = \gamma ma$. So $a = \frac{F}{m\gamma}$. Using the given numbers we get $a = 1.68 \times 10^{13}\ \text{m/s}^2$.

EVALUATE: Without relativity the acceleration would be $a = F/m = 5.39 \times 10^{13}\ \text{m/s}^2$, which is *greater* than when relativity it taken into account.

VP37.11.2. IDENTIFY: This problem is about the energy of a moving electron.

SET UP and EXECUTE: (a) We want the kinetic energy. $E = K + mc^2$, so $K = E - mc^2$
$= 4.00 \times 10^{-13}\ \text{J} + (9.11 \times 10^{-31}\ \text{kg})c^2 = 3.18 \times 10^{-13}\ \text{J}.$

(b) We want γ. $E = m\gamma c^2$. Solve for γ and use the given numbers. $\gamma = \frac{E}{mc^2} = 4.88.$

(c) We want the speed. Solve $\gamma = \dfrac{1}{\sqrt{1-v^2/c^2}}$ for v. $v/c = \sqrt{1-1/\gamma^2} = \sqrt{1-1/4.88^2} = 0.979$, so $v = 0.979c$.

EVALUATE: At speeds near the speed of light, the kinetic energy is much different from $\frac{1}{2}mv^2$.

VP37.11.3. IDENTIFY: This problem is about the energy of a moving electron.

SET UP: $E^2 = (pc)^2 + \left(mc^2\right)^2$, $E = m\gamma c^2$, $v/c = \sqrt{1-1/\gamma^2}$.

EXECUTE: **(a)** We want the total energy E. Solve $E^2 = (pc)^2 + \left(mc^2\right)^2$ for E and use the given numbers for the momentum p and rest mass m. The result is $E = 1.13\times10^{-13}$ J.

(b) We want γ. Solve $E = m\gamma c^2$ for γ and use the given m and E we found in (a), giving $\gamma = 1.38$.

(c) We want the speed v. $v/c = \sqrt{1-1/\gamma^2} = \sqrt{1-1/1.38^2} = 0.689$, so $v = 0.689c$.

EVALUATE: Careful! $E \neq pc + mc^2$.

VP37.11.4 IDENTIFY: This problem is about energy in particle decay.

SET UP: The $\psi(2S)$ is at rest, so by momentum conservation the K mesons have equal but opposite momentum and therefore equal speeds and equal kinetic energies. $mc^2 = 495$ MeV for each K meson. $E = K + mc^2$, $K = (\gamma-1)mc^2$.

EXECUTE: **(a)** We want the kinetic energy K of each meson. Using $E = K + mc^2$ gives $3686\text{ MeV} = (K + 495\text{ MeV}) + (K + 495\text{ MeV})$. Solving gives $K = 1348$ MeV for each meson.

(b) We want γ. $K = (\gamma-1)mc^2 = (\gamma-1)(495\text{ MeV})$. Solve for γ and use $K = 1348$ MeV from part (a), giving $\gamma = 3.72$.

(c) We want the speed. $v/c = \sqrt{1-1/\gamma^2} = \sqrt{1-1/3.72^2} = 0.963$, so $v = 0.963c$.

EVALUATE: The K^+ and K^- mesons are highly relativistic with $v = 0.963c$ and $\gamma = 3.72$.

37.1. IDENTIFY and SET UP: Consider the distance A to O' and B to O' as observed by an observer on the ground (Figure 37.1).

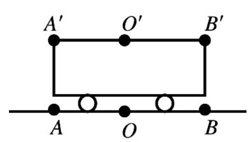

Figure 37.1

EXECUTE: The statement that the events are simultaneous to an observer on the train means that light pulses from A' and B' arrive at O' at the same time. To the observer at O, light from A' has a longer distance to travel than light from B' so O will conclude that the pulse from $A(A')$ started before the pulse at $B(B')$. To the observer at O, bolt A appeared to strike first.

EVALUATE: Section 37.2 shows that if the events are simultaneous to the observer on the ground, then an observer on the train measures that the bolt at B' struck first.

37.2. IDENTIFY: Apply $\Delta t = \gamma \Delta t_0$.

SET UP: The lifetime measured in the muon frame is the proper time Δt_0. $u = 0.900c$ is the speed of the muon frame relative to the laboratory frame. The distance the particle travels in the lab frame is its speed in that frame times its lifetime in that frame.

EXECUTE: **(a)** $\gamma = \dfrac{1}{\sqrt{1-(0.9)^2}} = 2.29.$ $\Delta t = \gamma \Delta t_0 = (2.29)\,(2.20\times 10^{-6}\text{s}) = 5.05\times 10^{-6}$ s.

(b) $d = v\Delta t = (0.900)(3.00\times 10^8 \text{ m/s})(5.05\times 10^{-6}\text{s}) = 1.36\times 10^3 \text{ m} = 1.36 \text{ km}.$

EVALUATE: The lifetime measured in the lab frame is larger than the lifetime measured in the muon frame.

37.3. **IDENTIFY** and **SET UP:** The problem asks for u such that $\Delta t_0/\Delta t = \frac{1}{2}$.

EXECUTE: $\Delta t = \dfrac{\Delta t_0}{\sqrt{1-u^2/c^2}}$ gives $u = c\sqrt{1-(\Delta t_0/\Delta t)^2} = (3.00\times 10^8 \text{ m/s})\sqrt{1-(\frac{1}{2})^2} = 2.60\times 10^8$ m/s;

$\dfrac{u}{c} = 0.867.$

EVALUATE: Jet planes fly at less than ten times the speed of sound, less than about 3000 m/s. Jet planes fly at much lower speeds than we calculated for u.

37.4. **IDENTIFY:** Time dilation occurs because the rocket is moving relative to Mars.

SET UP: The time dilation equation is $\Delta t = \gamma \Delta t_0$, where t_0 is the proper time.

EXECUTE: **(a)** The two time measurements are made at the same place on Mars by an observer at rest there, so the observer on Mars measures the proper time.

(b) $\Delta t = \gamma \Delta t_0 = \dfrac{1}{\sqrt{1-(0.985)^2}}(75.0\ \mu\text{s}) = 435\ \mu\text{s}.$

EVALUATE: The pulse lasts for a longer time relative to the rocket than it does relative to the Mars observer.

37.5. **(a) IDENTIFY** and **SET UP:** $\Delta t_0 = 2.60\times 10^{-8}$ s; $\Delta t = 4.20\times 10^{-7}$ s. In the lab frame the pion is created and decays at different points, so this time is not the proper time.

EXECUTE: $\Delta t = \dfrac{\Delta t_0}{\sqrt{1-u^2/c^2}}$ says $1-\dfrac{u^2}{c^2} = \left(\dfrac{\Delta t_0}{\Delta t}\right)^2.$

$$\frac{u}{c} = \sqrt{1-\left(\frac{\Delta t_0}{\Delta t}\right)^2} = \sqrt{1-\left(\frac{2.60\times 10^{-8}\text{ s}}{4.20\times 10^{-7}\text{ s}}\right)^2} = 0.998;\ u = 0.998c.$$

EVALUATE: $u < c$, as it must be, but u/c is close to unity and the time dilation effects are large.

(b) IDENTIFY and **SET UP:** The speed in the laboratory frame is $u = 0.998c$; the time measured in this frame is Δt, so the distance as measured in this frame is $d = u\Delta t$.

EXECUTE: $d = (0.998)(2.998\times 10^8 \text{ m/s})(4.20\times 10^{-7}\text{ s}) = 126 \text{ m}.$

EVALUATE: The distance measured in the pion's frame will be different because the time measured in the pion's frame is different (shorter).

37.6. **IDENTIFY:** Apply $\Delta t = \gamma \Delta t_0$.

SET UP: For part (a) the proper time is measured by the race pilot. $\gamma = 1.667$.

EXECUTE: **(a)** $\Delta t = \dfrac{1.20\times 10^8 \text{ m}}{(0.800)(3.00\times 10^8 \text{ m/s})} = 0.500$ s. $\Delta t_0 = \dfrac{\Delta t}{\gamma} = \dfrac{0.500\text{ s}}{1.667} = 0.300$ s.

(b) $(0.300\text{ s})(0.800c) = 7.20\times 10^7 \text{ m}.$

(c) You read $\dfrac{1.20\times 10^8 \text{ m}}{(0.800)(3\times 10^8 \text{ m/s})} = 0.500$ s.

EVALUATE: The two events are the spaceracer passing you and the spaceracer reaching a point 1.20×10^8 m from you. The timer traveling with the spaceracer measures the proper time between these two events.

37.7. **IDENTIFY** and **SET UP:** The proper time is measured in the frame where the two events occur at the same point.

EXECUTE: **(a)** The time of 12.0 ms measured by the first officer on the craft is the proper time.

(b) $\Delta t = \dfrac{\Delta t_0}{\sqrt{1-u^2/c^2}}$ gives $u = c\sqrt{1-(\Delta t_0/\Delta t)^2} = c\sqrt{1-(12.0\times10^{-3}/0.150)^2} = 0.997c.$

EVALUATE: The observer at rest with respect to the searchlight measures a much shorter duration for the event.

37.8. **IDENTIFY:** This problem involves time dilation.

SET UP: $\Delta t = \gamma\Delta t_0$. The captain's time is the proper time. We want x and t in our frame.

EXECUTE: $\Delta t = \gamma\Delta t_0 = (100)(1.00 \text{ s}) = 100$ s. $x = vt \approx ct = c(100 \text{ s}) = 3.00\times10^{10}$ s.

EVALUATE: Note that $v \approx c$, not $v = c$. But with $\gamma = 100$, the speed is *extremely* close to c.

37.9. **IDENTIFY** and **SET UP:** $l = l_0\sqrt{1-u^2/c^2}$. The length measured when the spacecraft is moving is $l = 74.0$ m; l_0 is the length measured in a frame at rest relative to the spacecraft.

EXECUTE: $l_0 = \dfrac{l}{\sqrt{1-u^2/c^2}} = \dfrac{74.0 \text{ m}}{\sqrt{1-(0.600c/c)^2}} = 92.5 \text{ m}.$

EVALUATE: $l_0 > l$. The moving spacecraft appears to an observer on the planet to be shortened along the direction of motion.

37.10. **IDENTIFY** and **SET UP:** When the meterstick is at rest with respect to you, you measure its length to be 1.000 m, and that is its proper length, l_0. $l = 0.3048$ m.

EXECUTE: $l = l_0\sqrt{1-u^2/c^2}$ gives $u = c\sqrt{1-(l/l_0)^2} = c\sqrt{1-(0.3048/1.00)^2} = 0.9524c = 2.86\times10^8$ m/s.

EVALUATE: The needed speed is well beyond modern capabilities for any rocket.

37.11. **IDENTIFY** and **SET UP:** The 2.2 μs lifetime is Δt_0 and the observer on earth measures Δt. The atmosphere is moving relative to the muon so in its frame the height of the atmosphere is l and l_0 is 10 km.

EXECUTE: **(a)** The greatest speed the muon can have is c, so the greatest distance it can travel in 2.2×10^{-6} s is $d = vt = (3.00\times10^8 \text{ m/s})(2.2\times10^{-6} \text{ s}) = 660 \text{ m} = 0.66 \text{ km}$.

(b) $\Delta t = \dfrac{\Delta t_0}{\sqrt{1-u^2/c^2}} = \dfrac{2.2\times10^{-6} \text{ s}}{\sqrt{1-(0.999)^2}} = 4.9\times10^{-5} \text{ s}.$

$d = vt = (0.999)(3.00\times10^8 \text{ m/s})(4.9\times10^{-5} \text{ s}) = 15 \text{ km}.$

In the frame of the earth the muon can travel 15 km in the atmosphere during its lifetime.

(c) $l = l_0\sqrt{1-u^2/c^2} = (10 \text{ km})\sqrt{1-(0.999)^2} = 0.45 \text{ km}.$

EVALUATE: In the frame of the muon the height of the atmosphere is less than the distance it moves during its lifetime.

37.12. **IDENTIFY:** The astronaut lies along the motion of the rocket, so his height will be Lorentz-contracted.

SET UP: The doctor in the rocket measures his proper length l_0.

EXECUTE: **(a)** $l_0 = 2.00$ m. $l = l_0\sqrt{1-u^2/c^2} = (2.00 \text{ m})\sqrt{1-(0.910)^2} = 0.829$ m. The person on Earth would measure his height to be 0.829 m.

(b) $l = 2.00$ m. $l_0 = \dfrac{l}{\sqrt{1-u^2/c^2}} = \dfrac{2.00 \text{ m}}{\sqrt{1-(0.910)^2}} = 4.82$ m. This is not a reasonable height for a human.

(c) There is no length contraction in a direction perpendicular to the motion and both observers measure the same height, 2.00 m.

EVALUATE: The length of an object moving with respect to the observer is shortened in the direction of the motion, so in (a) and (b) the observer on Earth measures a shorter height.

37.13. IDENTIFY: Apply $l = l_0\sqrt{1-u^2/c^2}$.

SET UP: The proper length l_0 of the runway is its length measured in the Earth's frame. The proper time Δt_0 for the time interval for the spacecraft to travel from one end of the runway to the other is the time interval measured in the frame of the spacecraft.

EXECUTE: **(a)** $l_0 = 3600$ m.

$$l = l_0\sqrt{1-\frac{u^2}{c^2}} = (3600\text{ m})\sqrt{1-\frac{(4.00\times10^7\text{ m/s})^2}{(3.00\times10^8\text{ m/s})^2}} = (3600\text{ m})(0.991) = 3568\text{ m}.$$

(b) $\Delta t = \dfrac{l_0}{u} = \dfrac{3600\text{ m}}{4.00\times10^7\text{ m/s}} = 9.00\times10^{-5}$ s.

(c) $\Delta t_0 = \dfrac{l}{u} = \dfrac{3568\text{ m}}{4.00\times10^7\text{ m/s}} = 8.92\times10^{-5}$ s.

EVALUATE: $\dfrac{1}{\gamma} = 0.991$, so $\Delta t = \gamma\Delta t_0$ gives $\Delta t = \dfrac{8.92\times10^{-5}\text{s}}{0.991} = 9.00\times10^{-5}$ s. The result from length contraction is consistent with the result from time dilation.

37.14. IDENTIFY: This problems requires use of the Lorentz transformation equations.

SET UP: $t' = \gamma\left(t - xu/c^2\right)$, $t = \gamma\left(t' + x'u/c^2\right)$. We want to know for what values x and x' will t be equal to t'.

EXECUTE: Using $t' = \gamma\left(t - xu/c^2\right)$, let $t = t'$ and solve for x. $t(\gamma-1) = xu\gamma/c^2$.

$x = \dfrac{c^2t(\gamma-1)}{u\gamma} = \dfrac{c^2t}{u}\left(1-\dfrac{1}{\gamma}\right)$. Now find x'. $t' = \gamma\left(t - xu/c^2\right)$ and $t = \gamma\left(t' + x'u/c^2\right)$ If $t = t'$, then it follows that $x'u/c^2 = -xu/c^2$, so $x' = -x$.

EVALUATE: The clocks are coordinated since $t = t'$.

37.15. IDENTIFY: Apply $v_x = \dfrac{v'_x + u}{1+uv'_x/c^2}$.

SET UP: The velocities $\vec{v}'$ and $\vec{v}$ are both in the $+x$-direction, so $v'_x = v'$ and $v_x = v$.

EXECUTE: **(a)** $v = \dfrac{v'+u}{1+uv'/c^2} = \dfrac{0.400c+0.600c}{1+(0.400)(0.600)} = 0.806c$.

(b) $v = \dfrac{v'+u}{1+uv'/c^2} = \dfrac{0.900c+0.600c}{1+(0.900)(0.600)} = 0.974c$.

(c) $v = \dfrac{v'+u}{1+uv'/c^2} = \dfrac{0.990c+0.600c}{1+(0.990)(0.600)} = 0.997c$.

EVALUATE: Speed v is always less than c, even when $v'+u$ is greater than c.

37.16. IDENTIFY: Apply $\Delta t = \gamma\Delta t_0$ and the equations for x and t that are developed in Example 37.6.

SET UP: S is Stanley's frame and S' is Mavis's frame. The proper time for the two events is the time interval measured in Mavis's frame. $\gamma = 1.667$ ($\gamma = 5/3$ if $u = (4/5)$c).

EXECUTE: **(a)** In Mavis's frame the event "light on" has space-time coordinates $x' = 0$ and $t' = 5.00$ s, so from the result of Example 37.6, $x = \gamma(x' + ut')$ and

$$t = \gamma\left(t' + \frac{ux'}{c^2}\right) \Rightarrow x = \gamma ut' = 2.00\times10^9\text{m}, t = \gamma t' = 8.33\text{ s}.$$

(b) The 5.00-s interval in Mavis's frame is the proper time Δt_0, so $\Delta t = \gamma \Delta t_0 = 8.33\text{ s}$, the same as in part (a).

(c) $(8.33\text{ s})(0.800c) = 2.00 \times 10^9\text{ m}$, which is the distance x found in part (a).

EVALUATE: Mavis would measure that she would be a distance $(5.00\text{ s})(0.800c) = 1.20 \times 10^9\text{ m}$ from Stanley when she turns on her light. In $l = l_0/\gamma$, $l_0 = 2.00 \times 10^9\text{ m}$ and $l = 1.20 \times 10^9\text{ m}$.

37.17. IDENTIFY: The relativistic velocity addition formulas apply since the speeds are close to that of light.

SET UP: The relativistic velocity addition formula is $v'_x = \dfrac{v_x - u}{1 - \dfrac{uv_x}{c^2}}$.

EXECUTE: **(a)** For the pursuit ship to catch the cruiser, the distance between them must be decreasing, so the velocity of the cruiser relative to the pursuit ship must be directed toward the pursuit ship.

(b) Let the unprimed frame be Tatooine and let the primed frame be the pursuit ship. We want the velocity v' of the cruiser knowing the velocity of the primed frame u and the velocity of the cruiser v in the unprimed frame (Tatooine). $v'_x = \dfrac{v_x - u}{1 - \dfrac{uv_x}{c^2}} = \dfrac{0.600c - 0.800c}{1 - (0.600)(0.800)} = -0.385c$.

The result implies that the cruiser is moving toward the pursuit ship at $0.385c$.

EVALUATE: The nonrelativistic formula would have given $-0.200c$, which is considerably different from the correct result.

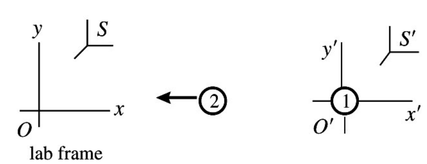
37.18. IDENTIFY and SET UP: Let the starfighter's frame be S and let the enemy spaceship's frame be S'. Let the positive x-direction for both frames be from the enemy spaceship toward the starfighter. Then $u = +0.400c$. $v' = +0.700c$. v is the velocity of the missile relative to you.

EXECUTE: **(a)** $v = \dfrac{v' + u}{1 + uv'/c^2} = \dfrac{0.700c + 0.400c}{1 + (0.400)(0.700)} = 0.859c$.

(b) Use the distance it moves as measured in your frame and the speed it has in your frame to calculate the time it takes in your frame. $t = \dfrac{8.00 \times 10^9\text{ m}}{(0.859)(3.00 \times 10^8\text{ m/s})} = 31.0\text{ s}$.

EVALUATE: Note that the speed in (a) is not $1.1c$ as nonrelativistic physics would predict.

37.19. IDENTIFY and SET UP: Reference frames S and S' are shown in Figure 37.19.



Frame S is at rest in the laboratory. Frame S' is attached to particle 1.

Figure 37.19

u is the speed of S' relative to S; this is the speed of particle 1 as measured in the laboratory. Thus $u = +0.650c$. The speed of particle 2 in S' is $0.950c$. Also, since the two particles move in opposite directions, 2 moves in the $-x'$-direction and $v'_x = -0.950c$. We want to calculate v_x, the speed of particle 2 in frame S, so use $v_x = \dfrac{v'_x + u}{1 + uv'_x/c^2}$.

EXECUTE: $v_x = \dfrac{v'_x + u}{1 + uv'_x/c^2} = \dfrac{-0.950c + 0.650c}{1 + (0.650c)(-0.950c)/c^2} = \dfrac{-0.300c}{1 - 0.6175} = -0.784c$. The speed of the second particle, as measured in the laboratory, is $0.784c$.

EVALUATE: The incorrect Galilean expression for the relative velocity gives that the speed of the second particle in the lab frame is $0.300c$. The correct relativistic calculation gives a result more than twice this.

37.20. **IDENTIFY** and **SET UP:** Let S be the laboratory frame and let S' be the frame of one of the particles, as shown in Figure 37.20. Let the positive x-direction for both frames be from particle 1 to particle 2. In the lab frame particle 1 is moving in the $+x$-direction and particle 2 is moving in the $-x$-direction. Then $u = 0.9380c$ and $v_x = -0.9380c$. v'_x is the velocity of particle 2 relative to particle 1.

EXECUTE: $v'_x = \dfrac{v_x - u}{1 - uv_x/c^2} = \dfrac{-0.9380c - 0.9380c}{1-(0.9380c)(-0.9380c)/c^2} = -0.9980c.$ The speed of particle 2 relative to particle 1 is $0.9980c$.

EVALUATE: $v'_x < 0$ shows particle 2 is moving toward particle 1.

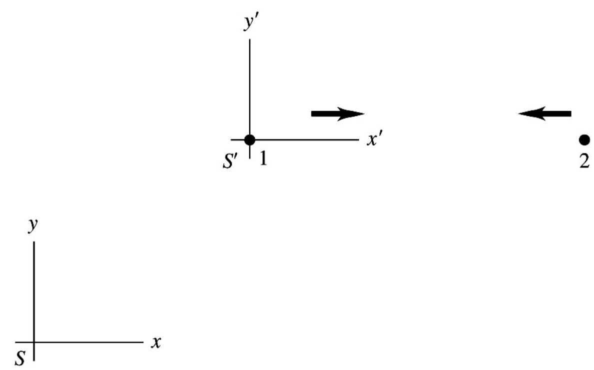


Figure 37.20

37.21. **IDENTIFY:** The relativistic velocity addition formulas apply since the speeds are close to that of light.

SET UP: The relativistic velocity addition formula is $v'_x = \dfrac{v_x - u}{1 - \dfrac{uv_x}{c^2}}$.

EXECUTE: In the relativistic velocity addition formula for this case, v'_x is the relative speed of particle 1 with respect to particle 2, v is the speed of particle 2 measured in the laboratory, and u is the speed of particle 1 measured in the laboratory, $u = -v$.

$v'_x = \dfrac{v-(-v)}{1-(-v)v/c^2} = \dfrac{2v}{1+v^2/c^2}$. $\dfrac{v'_x}{c^2}v^2 - 2v + v'_x = 0$ and $(0.890c)v^2 - 2c^2v + (0.890c^3) = 0.$

This is a quadratic equation with solution $v = 0.611c$ (v must be less than c).

EVALUATE: The nonrelativistic result would be $0.445c$, which is considerably different from this result.

37.22. **IDENTIFY:** There is a Doppler effect in the frequency of the radiation due to the motion of the star.

SET UP: The star is moving away from the earth, so $f = \sqrt{\dfrac{c-u}{c+u}}f_0$.

EXECUTE: $f = \sqrt{\dfrac{c-0.520c}{c+0.520c}}f_0 = 0.5620f_0 = (0.5620)(8.64\times10^{14}\text{ Hz}) = 4.86\times10^{14}\text{ Hz}.$

EVALUATE: The earth observer measures a lower frequency than the star emits because the star is moving away from the earth.

37.23. IDENTIFY and SET UP: Source and observer are approaching, so use $f=\sqrt{\dfrac{c+u}{c-u}}f_0$. Solve for u, the speed of the light source relative to the observer.

EXECUTE: **(a)** $f^2=\left(\dfrac{c+u}{c-u}\right)f_0^2$.

$(c-u)f^2=(c+u)f_0^2$ and $u=\dfrac{c(f^2-f_0^2)}{f^2+f_0^2}=c\left(\dfrac{(f/f_0)^2-1}{(f/f_0)^2+1}\right)$.

$\lambda_0=675\text{ nm},\ \ \lambda=575\text{ nm}.$

$u=\left(\dfrac{(675\text{ nm}/575\text{ nm})^2-1}{(675\text{ nm}/575\text{ nm})^2+1}\right)c=0.159c=(0.159)(2.998\times10^8\text{ m/s})=4.77\times10^7\text{ m/s};$ definitely speeding

(b) $4.77\times10^7\text{ m/s}=(4.77\times10^7\text{ m/s})(1\text{ km}/1000\text{ m})(3600\text{ s}/1\text{ h})=1.72\times10^8\text{ km/h}$. Your fine would be $\$1.72\times10^8$ (172 million dollars).

EVALUATE: The source and observer are approaching, so $f>f_0$ and $\lambda<\lambda_0$. Our result gives $u<c$, as it must.

37.24. IDENTIFY: There is a Doppler effect in the frequency of the radiation due to the motion of the source.

SET UP: $f>f_0$ so the source is moving toward you. $f=\sqrt{\dfrac{c-u}{c+u}}f_0$.

EXECUTE: $(f/f_0)^2=\dfrac{c+u}{c-u}$. $c(f/f_0)^2-(f/f_0)^2u=c+u$.

$u=\dfrac{c[(f/f_0)^2-1]}{(f/f_0)^2+1}=\left[\dfrac{(1.25)^2-1}{(1.25)^2+1}\right]c=0.220c$, toward you.

EVALUATE: The difference in frequency is rather large (1.25 times), so the motion of the source must be a substantial fraction of the speed of light (around 20% in this case).

37.25. IDENTIFY: The problem involves momentum and the Lorentz factor.

SET UP: $p=m\gamma v$, $\gamma=\dfrac{1}{\sqrt{1-u^2/c^2}}$, $u/c=\sqrt{1-1/\gamma^2}$, particle 1: $\gamma_1=1.12$, particle 2: $u_2=2u_1$.

EXECUTE: **(a)** We want γ_2. First find u_1. $u_1=c\sqrt{1-1/\gamma^2}=c\sqrt{1-1/1.12^2}=0.450343c$, so $u_2=2u_1$ $=0.90068c$. $\gamma_2=\dfrac{1}{\sqrt{1-(0.90068)^2}}=2.30.$

(b) We want p_2/p_1. $\dfrac{p_2}{p_1}=\dfrac{m\gamma_2u_2}{m\gamma_1u_1}=\dfrac{\gamma_2(2u_1)}{\gamma_1u_1}=\dfrac{2\gamma_2}{\gamma_1}=\dfrac{2(2.30)}{1.12}=4.11.$

EVALUATE: For speeds much less than that of light, we would have $p_2=2p_1$, but near the speed of light we find $p_2=4.11p_1$, a very significant difference.

37.26. IDENTIFY and SET UP: The force is found from $F=\gamma^3ma$ or $F=\gamma ma$, whichever is applicable.

EXECUTE: **(a)** Indistinguishable from $F=ma=0.145\text{ N}$.

(b) $\gamma^3ma=1.75\text{ N}$.

(c) $\gamma^3ma=51.7\text{ N}$.

(d) $\gamma ma=0.145\text{ N},\ 0.333\text{ N}, 1.03\text{ N}$.

EVALUATE: When v is large, much more force is required to produce a given magnitude of acceleration when the force is parallel to the velocity than when the force is perpendicular to the velocity.

37.27. IDENTIFY: The speed of the proton is a substantial fraction of the speed of light, so we must use the relativistic formula for momentum.

SET UP: $p = \gamma mv$. $p_0 = \gamma_0 m v_0$. $\dfrac{p}{p_0} = \dfrac{\gamma v}{\gamma_0 v_0}$. $v/v_0 = 2.00$.

EXECUTE: $\gamma_0 = \dfrac{1}{\sqrt{1 - v_0^2/c^2}} = \dfrac{1}{\sqrt{1-(0.400)^2}} = 1.0911$. $\gamma = \dfrac{1}{\sqrt{1-(0.800)^2}} = 1.667$.

$p = p_0(2)\left(\dfrac{1.667}{1.091}\right) = 3.06 p_0$.

EVALUATE: The speed doubles but the momentum more than triples.

37.28. IDENTIFY: In this problem we deal with length contraction and momentum.

SET UP: $L = L_0/\gamma$, $p = m\gamma v$, $v/c = \sqrt{1 - 1/\gamma^2}$. We measure L = 90 m, but its proper length is 120 m.

EXECUTE: **(a)** The diameter will be 25 m. There is no length contraction perpendicular to the direction of motion.

(b) We want the momentum p. Use length contraction to find γ. $L = L_0/\gamma$: 90 m = (120 m)/ γ, so γ = 1.33. Now use γ to find v. $v/c = \sqrt{1-1/\gamma^2} = \sqrt{1-1/1.33^2} = 0.6614$. Now use $p = m\gamma v$ to find p.

$p = m\gamma v$ = (4000 kg)(133)(0.6614c) = 1.1×10^{12} kg $\cdot$ m/s.

EVALUATE: Ignoring relativity we would measure a length of 120 m and a momentum of $p = mv$ = (4000 kg)(0.6614c) = 7.9×10^{11} kg $\cdot$ m/s. A big difference from the actual momentum!

37.29. IDENTIFY: Apply $p = \dfrac{mv}{\sqrt{1 - v^2/c^2}}$ and $F = \gamma^3 ma$.

SET UP: For a particle at rest (or with $v \ll c$), $a = F/m$.

EXECUTE: **(a)** $p = \dfrac{mv}{\sqrt{1-v^2/c^2}} = 2mv$.

$\Rightarrow 1 = 2\sqrt{1 - v^2/c^2} \Rightarrow \frac{1}{4} = 1 - \dfrac{v^2}{c^2} \Rightarrow v^2 = \frac{3}{4}c^2 \Rightarrow v = \dfrac{\sqrt{3}}{2}c = 0.866c$.

(b) $F = \gamma^3 ma = 2ma \Rightarrow \gamma^3 = 2 \Rightarrow \gamma = (2)^{1/3}$ so $\dfrac{1}{1 - v^2/c^2} = 2^{2/3} \Rightarrow \dfrac{v}{c} = \sqrt{1 - 2^{-2/3}} = 0.608$.

EVALUATE: The momentum of a particle and the force required to give it a given acceleration both increase without bound as the speed of the particle approaches c.

37.30. IDENTIFY: Use $E = mc^2$ to relate the mass decrease to the energy produced.

SET UP: 1 kg is equivalent to 2.2 lbs and 1 ton = 2000 lbs. 1 W = 1 J/s.

EXECUTE: **(a)** $E = mc^2, m = E/c^2 = (3.8\times 10^{26}\text{ J})/(2.998\times 10^8\text{ m/s})^2 = 4.2\times 10^9\text{ kg} = 4.6\times 10^6$ tons.

(b) The current mass of the sun is 1.99×10^{30} kg, so it would take it

$(1.99\times 10^{30}\text{ kg})/(4.2\times 10^9\text{ kg/s}) = 4.7\times 10^{20}\text{s} = 1.5\times 10^{13}$ years to use up all its mass.

EVALUATE: The power output of the sun is very large, but only a small fraction of the sun's mass is converted to energy each second.

37.31. IDENTIFY: Apply $K = \dfrac{mc^2}{\sqrt{1 - v^2/c^2}} - mc^2$.

SET UP: The rest energy is mc^2.

EXECUTE: **(a)** $K = \dfrac{mc^2}{\sqrt{1-v^2/c^2}} - mc^2 = mc^2$.

$$\Rightarrow \frac{1}{\sqrt{1-v^2/c^2}} = 2 \Rightarrow \frac{1}{4} = 1 - \frac{v^2}{c^2} \Rightarrow v = \sqrt{\frac{3}{4}}c = 0.866c.$$

(b) $K = 5mc^2 \Rightarrow \dfrac{1}{\sqrt{1-v^2/c^2}} = 6 \Rightarrow \dfrac{1}{36} = 1 - \dfrac{v^2}{c^2} \Rightarrow v = \sqrt{\dfrac{35}{36}}c = 0.986c.$

EVALUATE: If $v \ll c$, then K is much less than the rest energy of the particle.

37.32. **IDENTIFY:** At such a high speed, we must use the relativistic formulas for momentum and kinetic energy.

SET UP: $m_\mu = 207m_e = 1.89\times10^{-28}$ kg. v is very close to c and we must use relativistic expressions.

$$p = \frac{mv}{\sqrt{1-v^2/c^2}},\quad K = \frac{mc^2}{\sqrt{1-v^2/c^2}} - mc^2.$$

EXECUTE: $p = \dfrac{mv}{\sqrt{1-v^2/c^2}} = \dfrac{(1.89\times10^{-28}\text{ kg})(0.999)(3.00\times10^8\text{ m/s})}{\sqrt{1-(0.999)^2}} = 1.27\times10^{-18}\text{ kg}\cdot\text{m/s}.$

Using $K = \dfrac{mc^2}{\sqrt{1-v^2/c^2}} - mc^2$ gives

$$K = (1.89\times10^{-28}\text{ kg})(3.00\times10^8\text{ m/s})^2\left(\frac{1}{\sqrt{1-(0.999)^2}} - 1\right) = 3.63\times10^{-10}\text{ J}.$$

EVALUATE: The nonrelativistic values are $p_{\text{nr}} = mv = 5.66\times10^{-20}\text{ kg}\cdot\text{m/s}$ and $K_{\text{nr}} = \frac{1}{2}mv^2$ $= 8.49\times10^{-12}$ J. Each relativistic result is much larger.

37.33. **IDENTIFY** and **SET UP:** Use $E = mc^2 + K$ and $E^2 = (mc^2)^2 + (pc)^2$.

EXECUTE: **(a)** $E = mc^2 + K$, so $E = 4.00mc^2$ means $K = 3.00mc^2 = 4.50\times10^{-10}$ J.

(b) $E^2 = (mc^2)^2 + (pc)^2$; $E = 4.00mc^2$, so $15.0(mc^2)^2 = (pc)^2$.

$p = \sqrt{15}mc = 1.94\times10^{-18}\text{ kg}\cdot\text{m/s}.$

(c) $E = mc^2/\sqrt{1-v^2/c^2}$.

$E = 4.00mc^2$ gives $1 - v^2/c^2 = 1/16$ and $v = \sqrt{15/16}c = 0.968c$.

EVALUATE: The speed is close to c since the kinetic energy is greater than the rest energy. Nonrelativistic expressions relating E, K, p, and v will be very inaccurate.

37.34. **IDENTIFY:** Apply the work energy theorem in the form $W = \Delta K$.

SET UP: K is given by $K = (\gamma - 1)mc^2$. When $v = 0$, $\gamma = 1$.

EXECUTE: **(a)** $W = \Delta K = (\gamma_f - 1)mc^2 = (4.07\times10^{-3})\,mc^2$.

(b) $(\gamma_f - \gamma_i)\,mc^2 = 4.79mc^2$.

(c) The result of part (b) is far larger than that of part (a).

EVALUATE: The amount of work required to produce a given increase in speed (in this case an increase of $0.090c$) increases as the initial speed increases.

37.35. **IDENTIFY** and **SET UP:** The total energy is given in terms of the momentum by $E^2=(mc^2)^2+(pc)^2$. In terms of the total energy E, the kinetic energy K is $K=E-mc^2$. The rest energy is mc^2.

EXECUTE: (a)

$$E=\sqrt{(mc^2)^2+(pc)^2}=\sqrt{\left[(6.64\times10^{-27})(2.998\times10^8)^2\right]^2+\left[(2.10\times10^{-18})(2.998\times10^8)\right]^2}\text{ J.}$$

$E=8.67\times10^{-10}$ J.

(b) $mc^2=(6.64\times10^{-27}\text{ kg})(2.998\times10^8\text{ m/s})^2=5.97\times10^{-10}$ J.

$K=E-mc^2=8.67\times10^{-10}\text{ J}-5.97\times10^{-10}\text{ J}=2.70\times10^{-10}$ J.

(c) $\dfrac{K}{mc^2}=\dfrac{2.70\times10^{-10}\text{ J}}{5.97\times10^{-10}\text{ J}}=0.452.$

EVALUATE: The incorrect nonrelativistic expressions for K and p give $K=p^2/2m=3.3\times10^{-10}$ J; the correct relativistic value is less than this.

37.36. **IDENTIFY:** With such a large potential difference, the electrons will be accelerated to relativistic speeds, so we must use the relativistic formula for kinetic energy.

SET UP: $K=\left(\dfrac{1}{\sqrt{1-v^2/c^2}}-1\right)mc^2$. The classical expression for kinetic energy is $K=\frac{1}{2}mv^2$.

EXECUTE: For an electron $mc^2=(9.11\times10^{-31}\text{ kg})(3.00\times10^8\text{ m/s})^2=8.20\times10^{-14}$ J.

$K=7.50\times10^5\text{ eV}=1.20\times10^{-13}$ J.

(a) $\dfrac{K}{mc^2}+1=\dfrac{1}{\sqrt{1-v^2/c^2}}$. $\dfrac{1}{\sqrt{1-v^2/c^2}}=\dfrac{1.20\times10^{-13}\text{ J}}{8.20\times10^{-14}\text{ J}}+1=2.46.$

$v=c\sqrt{1-(1/2.46)^2}=0.914c=2.74\times10^8$ m/s.

(b) $K=\frac{1}{2}mv^2$ gives $v=\sqrt{\dfrac{2K}{m}}=\sqrt{\dfrac{2(1.20\times10^{-13}\text{ J})}{9.11\times10^{-31}\text{ kg}}}=5.13\times10^8$ m/s.

EVALUATE: At a given speed the relativistic value of the kinetic energy is larger than the nonrelativistic value. Therefore, for a given kinetic energy the relativistic expression for kinetic energy gives a smaller speed than the nonrelativistic expression.

37.37. **IDENTIFY** and **SET UP:** The nonrelativistic expression is $K_{\text{nonrel}}=\frac{1}{2}mv^2$ and the relativistic expression is $K_{\text{rel}}=(\gamma-1)mc^2$.

EXECUTE: (a) $v=8\times10^7\text{ m/s}\Rightarrow\gamma=\dfrac{1}{\sqrt{1-v^2/c^2}}=1.0376.$ For $m=m_{\text{p}}$, $K_{\text{nonrel}}=\frac{1}{2}mv^2=5.34\times10^{-12}$ J.

$K_{\text{rel}}=(\gamma-1)mc^2=5.65\times10^{-12}$ J. $\dfrac{K_{\text{rel}}}{K_{\text{nonrel}}}=1.06.$

(b) $v=2.85\times10^8$ m/s; $\gamma=3.203$.

$K_{\text{nonrel}}=\dfrac{1}{2}mv^2=6.78\times10^{-11}$ J; $K_{\text{rel}}=(\gamma-1)mc^2=3.31\times10^{-10}$ J; $K_{\text{rel}}/K_{\text{nonrel}}=4.88.$

EVALUATE: $K_{\text{rel}}/K_{\text{nonrel}}$ increases without bound as v approaches c.

37.38. **IDENTIFY:** The total energy is conserved in the collision.

SET UP: Use $E=mc^2+K$ for the total energy. Since all three particles are at rest after the collision, the final total energy is $2Mc^2+mc^2$. The initial total energy of the two protons is $\gamma 2Mc^2$.

EXECUTE: **(a)** $2Mc^2 + mc^2 = \gamma 2Mc^2 \Rightarrow \gamma = 1 + \frac{m}{2M} = 1 + \frac{9.75}{2(16.7)} = 1.292.$

Note that since $\gamma = \frac{1}{\sqrt{1 - v^2/c^2}}$, we have that $\frac{v}{c} = \sqrt{1 - \frac{1}{\gamma^2}} = \sqrt{1 - \frac{1}{(1.292)^2}} = 0.6331.$

(b) According to $K = (\gamma - 1)mc^2$ the kinetic energy of each proton is

$$K = (\gamma - 1)Mc^2 = (1.292 - 1)(1.67 \times 10^{-27}\ \text{kg})(3.00 \times 10^8\ \text{m/s})^2 \left(\frac{1.00\ \text{MeV}}{1.60 \times 10^{-13}\ \text{J}}\right) = 274\ \text{MeV}.$$

(c) The rest energy of η^0 is $mc^2 = (9.75 \times 10^{-28}\ \text{kg})(3.00 \times 10^8\ \text{m/s})^2 \left(\frac{1.00\ \text{MeV}}{1.60 \times 10^{-13}\ \text{J}}\right) = 548\ \text{MeV}.$

EVALUATE: **(d)** The kinetic energy lost by the protons is the energy that produces the η^0, $548\ \text{MeV} = 2(274\ \text{MeV})$.

37.39. **IDENTIFY** and **SET UP:** Use $K = q\Delta V = e\Delta V$ and conservation of energy to relate the potential difference to the kinetic energy gained by the electron. Use $K = mc^2\left(\frac{1}{\sqrt{1 - v^2/c^2}} - 1\right)$ to calculate the kinetic energy from the speed.

EXECUTE: **(a)** $K = q\Delta V = e\Delta V$.

$$K = mc^2\left(\frac{1}{\sqrt{1 - v^2/c^2}} - 1\right) = 4.025mc^2 = 3.295 \times 10^{-13}\ \text{J} = 2.06\ \text{MeV}.$$

$\Delta V = K/e = 2.06 \times 10^6$ V.

(b) From part (a), $K = 3.30 \times 10^{-13}\ \text{J} = 2.06\ \text{MeV}$.

EVALUATE: The speed is close to c and the kinetic energy is four times the rest mass.

37.40. **IDENTIFY** and **SET UP:** The astronaut in the spaceship measures the proper time, since the end of a swing occurs at the same location in his frame. $\Delta t = \frac{\Delta t_0}{\sqrt{1 - u^2/c^2}}$.

EXECUTE: **(a)** $\Delta t_0 = 1.80$ s. $\Delta t = \frac{\Delta t_0}{\sqrt{1 - u^2/c^2}} = \frac{1.80\ \text{s}}{\sqrt{1 - (0.75c/c)^2}} = 2.72$ s.

(b) $\Delta t = 1.80$ s. $\Delta t_0 = \Delta t\sqrt{1 - u^2/c^2} = (1.80\ \text{s})\sqrt{1 - (0.75c/c)^2} = 1.19$ s.

EVALUATE: The motion of the spaceship makes a considerable difference in the measured values for the period of the pendulum!

37.41. **IDENTIFY** and **SET UP:** There must be a length contraction such that the length a becomes the same as b; $l_0 = a$, $l = b$. l_0 is the distance measured by an observer at rest relative to the spacecraft. Use $l = l_0\sqrt{1 - u^2/c^2}$ and solve for u.

EXECUTE: $\frac{l}{l_0} = \sqrt{1 - u^2/c^2}$ so $\frac{b}{a} = \sqrt{1 - u^2/c^2}$;

$a = 1.40b$ gives $b/1.40b = \sqrt{1 - u^2/c^2}$. and thus $1 - u^2/c^2 = 1/(1.40)^2$.

$u = \sqrt{1 - 1/(1.40)^2}\,c = 0.700c = 2.10 \times 10^8$ m/s.

EVALUATE: A length on the spacecraft in the direction of the motion is shortened. A length perpendicular to the motion is unchanged.

37.42. **IDENTIFY** and **SET UP:** The proper length of a side is $l_0 = a$. The side along the direction of motion is shortened to $l = l_0\sqrt{1-v^2/c^2}$. The sides in the two directions perpendicular to the motion are unaffected by the motion and still have a length a.

EXECUTE: $V = a^2 l = a^3\sqrt{1-v^2/c^2}$.

EVALUATE: Only the side parallel to the direction of motion is contracted.

37.43. **IDENTIFY** and **SET UP:** The proper time Δt_0 is the time that elapses in the frame of the space probe. Δt is the time that elapses in the frame of the earth. The distance traveled is 42.2 light years, as measured in the earth frame.

EXECUTE: Light travels 42.2 light years in 42.2 y, so $\Delta t = \left(\dfrac{c}{0.9930c}\right)(42.2\text{ y}) = 42.5\text{ y}$.

$\Delta t_0 = \Delta t\sqrt{1-u^2/c^2} = (42.5\text{ y})\sqrt{1-(0.9930)^2} = 5.0\text{ y}$. She measures her biological age to be $19\text{ y} + 5.0\text{ y} = 24.0\text{ y}$.

EVALUATE: Her age measured by someone on earth is $19\text{ y} + 42.5\text{ y} = 61.5\text{ y}$.

37.44. **IDENTIFY:** This problem involves time dilation, energy, and momentum.

SET UP: $\Delta t = \gamma\Delta t_0$, $v/c = \sqrt{1-1/\gamma^2}$, $K = (\gamma-1)mc^2$. In the lab: $t_{\text{mean}} = 403$ ps, in the particle's frame: $t_{\text{mean}} = 80.2$ ps.

EXECUTE: **(a)** We want the speed. Use time dilation: $\Delta t = \gamma\Delta t_0$ gives $403\text{ ps} = \gamma(80.2\text{ ps})$, so $\gamma = 5.025$. Now get the speed: $v/c = \sqrt{1-1/\gamma^2} = \sqrt{1-1/5.025^2} = 0.980c$.

(b) We want Δx in the lab. $\Delta x = v\Delta t = (0.980c)(403\text{ ps}) = 11.8$ cm.

(c) We want its energies in the lab frame.

<u>Rest energy</u>: $E_{\text{rest}} = mc^2 = (2.12\times10^{-27}\text{ kg})c^2 = 1.91\times10^{-10}$ J.

<u>Kinetic energy</u>: $K = (\gamma-1)mc^2 = (5.025-1)(1.91\times10^{-10}\text{ J}) = 7.68\times10^{-10}$ J.

<u>Total energy</u>: $E_{\text{tot}} = K + E_{\text{rest}} = 7.68\times10^{-10}\text{ J} + 1.91\times10^{-10}\text{ J} = 9.59\times10^{-10}$ J.

(d) We want the energies in its rest frame. $K = 0$, so $E_{\text{tot}} = E_{\text{rest}} = 1.91\times10^{-10}$ J.

EVALUATE: Even for nonrelativistic motion, $K = 0$ in the particle's rest frame.

37.45. **IDENTIFY:** This problem involves relative velocity and mass.

SET UP: $m_{\text{rel}} = m\gamma = \dfrac{m}{\sqrt{1-u^2/c^2}}$, $v'_x = \dfrac{v_x - u}{1-uv_x/c^2}$. We want the mass of the standard kilogram.

EXECUTE: **(a)** In classical physics, mass doesn't change with speed, so both crews would measure 1.0 kg.

(b) <u>For A</u>: $m_{\text{rel}} = m\gamma_A = \dfrac{m}{\sqrt{1-u_A^2/c^2}} = \dfrac{1.00\text{ kg}}{\sqrt{1-0.80^2}} = 1.7$ kg.

<u>For B</u>: We need to find the speed of B relative to Earth. Use $v'_x = \dfrac{v_x - u}{1-uv_x/c^2}$, letting Earth be the primed frame and A the unprimed frame. We want v'. $v'_{B/E} = \dfrac{0.98c - 0.80c}{1-(0.98c)(0.80c)/c^2} = 0.833c$. The mass is

$$m_{\text{rel}} = \frac{m}{\sqrt{1-u_B^2/c^2}} = \frac{1.00\text{ kg}}{\sqrt{1-0.833^2}} = 1.8\text{ kg}.$$

EVALUATE: B measures a greater mass than A measures because B is moving faster relative to Earth than A is. Both of them, however, would measure 1.00 kg as the rest mass of the standard kilogram.

37.46. **IDENTIFY:** We are looking at a world in which c = 65 mph.
SET UP: The standard relativity equations all apply except that we use c = 65 mph. You are driving at 60 mph.
EXECUTE: **(a)** We want the time difference between the kitchen clock and the moving wristwatch.
Kitchen clock time: You drive 60 mi at 60 mph, so it would take 1.0 h.
Wristwatch time: Your time is the proper time. Use $\Delta t = \gamma\Delta t_0$.

$$\gamma = \frac{1}{\sqrt{1-u^2/c^2}} = \frac{1}{\sqrt{1-(60/65)^2}} = 2.60$$

$\Delta t_0 = \Delta t/\gamma =$ (1.0 h)/(2.60) = 0.38 h = 23 min
(b) Estimate: 15 ft long.
(c) We want its length L from a roadside observer. L_0 = 15 ft = proper length.
$L = L_0/\gamma =$ (15 ft)/(2.60) = 5.8 ft = 5 ft 9 in.
(d) We want the speed relative to you. Use $v'_x = \dfrac{v_x - u}{1 - uv_x/c^2}$, with your car being the primed frame and earth the unprimed frame. We want v'. $v' = \dfrac{-60 \text{ mph} - 60 \text{ mph}}{1-(60)(-60)/(65)^2} = 64.8$ mph.
(e) We want the car's length in your frame. $L = L_0\sqrt{1-u^2/c^2}$ = (15 ft)$\sqrt{1-64.8^2/65^2} = 1.2$ ft.
(f) We want the work to reach 60 mph. c = 65 mph = 29.055 m/s. $W = K = (\gamma - 1)mc^2$
$= (2.60-1)(2000 \text{ kg})(29.055 \text{ m/s})^2 = 2.7$ MJ.
(g) We want the work in the real world. Since 60 mph << c, we use $K = \dfrac{1}{2}mv^2$ with 60 mph = 26.82 m/s. This gives W = 720 kJ.
EVALUATE: Relativity would be obvious to us if we normally moved near the speed of light.

37.47. **IDENTIFY:** Since the speed is very close to the speed of light, we must use the relativistic formula for kinetic energy.
SET UP: The relativistic formula for kinetic energy is $K = mc^2\left(\dfrac{1}{\sqrt{1-v^2/c^2}} - 1\right)$ and the relativistic mass is $m_{\text{rel}} = \dfrac{m}{\sqrt{1-v^2/c^2}}$.
EXECUTE: **(a)** $K = 7.0\times10^{12}$ eV $= 1.12\times10^{-6}$ J. Using this value in the relativistic kinetic energy formula and substituting the mass of the proton for m, we get $K = mc^2\left(\dfrac{1}{\sqrt{1-v^2/c^2}} - 1\right)$ which gives $\dfrac{1}{\sqrt{1-v^2/c^2}} = 7.45\times10^3$ and $1 - \dfrac{v^2}{c^2} = \dfrac{1}{(7.45\times10^3)^2}$. Solving for v gives $1 - \dfrac{v^2}{c^2} = \dfrac{(c+v)(c-v)}{c^2} = \dfrac{2(c-v)}{c}$, since $c + v \approx 2c$. Substituting $v = (1-\Delta)c$, we have $1 - \dfrac{v^2}{c^2} = \dfrac{2(c-v)}{c} = \dfrac{2[c-(1-\Delta)c]}{c} = 2\Delta$. Solving for Δ gives $\Delta = \dfrac{1-v^2/c^2}{2} = \dfrac{\frac{1}{(7.45\times10^3)^2}}{2} = 9.0\times10^{-9}$.

(b) Using the relativistic mass formula and the result that $\dfrac{1}{\sqrt{1-v^2/c^2}} = 7.45\times10^3,$ we have

$$m_{\text{rel}} = \frac{m}{\sqrt{1-v^2/c^2}} = m\left(\frac{1}{\sqrt{1-v^2/c^2}}\right) = (7.5\times10^3)m.$$

EVALUATE: At such high speeds, the proton's mass is 7500 times as great as its rest mass.

37.48. **IDENTIFY** and **SET UP:** The acceleration parallel to the direction of the force is given by $F_{\|} = \gamma^3 ma_{\|},$ and the acceleration perpendicular to the direction of the force is given by $F_{\perp} = \gamma ma_{\perp},$ where $\gamma = 1/\sqrt{1-v^2/c^2}.$

EXECUTE: Applying the above formulas to the conditions of this problem, we have $\gamma = 1/\sqrt{1-(0.700)^2} = 1.400,$ $F_x = F\cos(30.0°) = \gamma^3 ma_x$ and $F_y = F\sin(30.0°) = \gamma ma_y$. The angle θ that the acceleration makes with respect to the x-axis is given by $\tan\theta = a_y/a_x$. Dividing the acceleration given by the two force equations gives

$$\tan\theta = \frac{\dfrac{F\sin(30.0°)}{\gamma m}}{\dfrac{F\cos(30.0°)}{\gamma^3 m}} = \gamma^2\tan(30.0°) = (1.400)^2\tan(30.0°) = 1.132 \quad\rightarrow\quad \theta = 48.5°.$$

The acceleration makes a counterclockwise angle of 48.5° from the $+x$-axis. Therefore it makes an angle of 18.5° counterclockwise from the direction of the force.

EVALUATE: Notice that the acceleration is not in the same direction as the force.

37.49. **IDENTIFY** and **SET UP:** The clock on the plane measures the proper time Δt_0.

$\Delta t = 4.00\text{ h} = (4.00\text{ h})(3600\text{ s}/1\text{ h}) = 1.44\times10^4\text{ s}.$

$\Delta t = \dfrac{\Delta t_0}{\sqrt{1-u^2/c^2}}$ and $\Delta t_0 = \Delta t\sqrt{1-u^2/c^2}.$

EXECUTE: $\dfrac{u}{c}$ small so $\sqrt{1-u^2/c^2} = (1-u^2/c^2)^{1/2} \approx 1-\tfrac{1}{2}\dfrac{u^2}{c^2};$ thus $\Delta t_0 = \Delta t\left(1-\dfrac{1}{2}\dfrac{u^2}{c^2}\right).$

The difference in the clock readings is

$\Delta t - \Delta t_0 = \tfrac{1}{2}\dfrac{u^2}{c^2}\Delta t = \tfrac{1}{2}\left(\dfrac{250\text{ m/s}}{2.998\times10^8\text{ m/s}}\right)^2(1.44\times10^4\text{ s}) = 5.01\times10^{-9}\text{ s}.$ The clock on the plane has the shorter elapsed time.

EVALUATE: Δt_0 is always less than $\Delta t;$ our results agree with this. The speed of the plane is much less than the speed of light, so the difference in the reading of the two clocks is very small.

37.50. **IDENTIFY:** In the rest frame of the spaceship the trip takes $\Delta t_0 = 3.35$ years.

SET UP: As seen from the Earth the trip takes $\Delta t = \dfrac{\Delta t_0}{\sqrt{1-u^2/c^2}}$. The distance to the star is 7.11 ly and the speed of light is $c = 1$ ly/y. Let u be the speed of the spaceship (in ly/y) as seen from the Earth.

EXECUTE: **(a)** The time for the trip as seen from the earth will be $\Delta t = \dfrac{7.11\text{ ly}}{u} = \dfrac{3.35\text{ y}}{\sqrt{1-u^2/c^2}}$. Solving for u we obtain $\left(\dfrac{7.11\text{ ly}}{3.35\text{ y}}\right)^2(1-u^2/c^2) = u^2,$ which reduces to

$u = \left(\dfrac{7.11\text{ ly}}{3.35\text{ y}}\right)\cdot\dfrac{1}{\sqrt{1+\left(\dfrac{7.11\text{ ly}}{(3.35\text{ y})(1\text{ ly/y})}\right)^2}} = 0.905\text{ ly/y} = 0.905c.$ Thus, as seen from the Earth, the trip takes $\dfrac{7.11\text{ ly}}{u} = \dfrac{7.11\text{ ly}}{0.905\text{ ly/y}} = 7.86$ years.

(b) According to the passengers the distance is given by $x' = u\Delta t_0 = (0.905\text{ ly/y})(3.35\text{ y}) = 3.03\text{ ly}.$

EVALUATE: The distance to the star as seen by the passengers could also be calculated by using the length contraction formula: $l = l_0\sqrt{1-u^2/c^2}$.

37.51. IDENTIFY and **SET UP:** In crown glass the speed of light is $v = \dfrac{c}{n}.$ Calculate the kinetic energy of an electron that has this speed.

EXECUTE: $v = \dfrac{2.998\times10^8\text{ m/s}}{1.52} = 1.972\times10^8\text{ m/s}.$

$K = mc^2(\gamma-1).$

$mc^2 = (9.109\times10^{-31}\text{ kg})(2.998\times10^8\text{ m/s})^2 = 8.187\times10^{-14}\text{ J}(1\text{ eV}/1.602\times10^{-19}\text{ J}) = 0.5111\text{ MeV}.$

$\gamma = \dfrac{1}{\sqrt{1-v^2/c^2}} = \dfrac{1}{\sqrt{1-((1.972\times10^8\text{ m/s})/(2.998\times10^8\text{ m/s}))^2}} = 1.328.$

$K = mc^2(\gamma-1) = (0.5111\text{ MeV})(1.328-1) = 0.168\text{ MeV}.$

EVALUATE: No object can travel faster than the speed of light in vacuum but there is nothing that prohibits an object from traveling faster than the speed of light in some material.

37.52. IDENTIFY: We use relativistic energy to investigate the quark model of the proton.

SET UP: $K = (\gamma-1)mc^2$, $v/c = \sqrt{1-1/\gamma^2}$, $\gamma = \dfrac{1}{\sqrt{1-u^2/c^2}}$.

EXECUTE: **(a)** We want γ_u. $m_pc^2 = 2K_u + K_d = 3K_u$. $K_u = \dfrac{1}{3}m_pc^2$ and $K_u = m_uc^2(\gamma_u-1).$ So $\dfrac{1}{3}m_pc^2 = m_uc^2(\gamma_u-1).$ Solve for γ_u using the given masses: $\gamma_u = 136$.

(b) We want γ_d. Use the same procedure as in (a), giving $\gamma_u = 65.8$.

(c) We want the speeds. $v_u/c = \sqrt{1-1/\gamma_u^2} = 0.99997,$ so the answer is yes. $v_d/c = \sqrt{1-1/\gamma_d^2} = 0.9999,$ so the answer is yes.

(d) We want to know what % of the proton mass is from gluons. $m_pc^2 = 2K_u + K_d + E_g$.

$\dfrac{E_g}{m_pc^2} = \dfrac{m_pc^2-(2K_u+K_d)}{m_pc^2} = \dfrac{m_p-2m_u(\gamma-1)-m_d(\gamma-1)}{m_p}.$ $\gamma = \dfrac{1}{\sqrt{1-u^2/c^2}} = \dfrac{1}{\sqrt{1-0.90^2}} = 2.294.$ Using this γ and the given masses gives $\dfrac{E_g}{m_pc^2} = 0.987 \approx 99\%.$

(e) We want to estimate the frequency f. If T is the time for one cycle of amp006Citude A at speed v, then $vT = 4A.$ $f = 1/T = 1/(4A/v) = v/4A.$ $A = \dfrac{1}{2}(1.7\times10^{-15}\text{ m}) = 8.5\times10^{-16}\text{ m}.$ Using this value with $v = 0.90c$ gives our estimate $f = 8\times10^{22}\text{ Hz} \approx 10^{23}\text{ Hz}.$

EVALUATE: Rough models such as this one do not give precise results, but they do provide approximate estimations than can be compared to experimental results.

37.53. **IDENTIFY** and **SET UP:** The energy released is $E = (\Delta m)c^2$. $\Delta m = \left(\frac{1}{10^4}\right)(12.0\text{ kg})$. $P_{\text{av}} = \frac{E}{t}$.

The change in gravitational potential energy is $mg\Delta y$.

EXECUTE: **(a)** $E = (\Delta m)c^2 = \left(\frac{1}{10^4}\right)(12.0\text{ kg})(3.00\times10^8\text{ m/s})^2 = 1.08\times10^{14}\text{ J}$.

(b) $P_{\text{av}} = \frac{E}{t} = \frac{1.08\times10^{14}\text{ J}}{4.00\times10^{-6}\text{ s}} = 2.70\times10^{19}\text{ W}$.

(c) $E = \Delta U = mg\Delta y$. $m = \frac{E}{g\Delta y} = \frac{1.08\times10^{14}\text{ J}}{(9.80\text{ m/s}^2)(1.00\times10^3\text{ m})} = 1.10\times10^{10}\text{ kg}$.

EVALUATE: The mass decrease is only 1.2 grams, but the energy released is very large.

37.54. **IDENTIFY:** The protons are moving at speeds that are comparable to the speed of light, so we must use the relativistic velocity addition formula.

SET UP: S is lab frame and S' is frame of proton moving in $+x$-direction. $v_x = -0.700c$. In lab frame each proton has speed αc. $u = +\alpha c$. $v_x = -\alpha c$. $v_x = \frac{v'_x + u}{1 + uv'_x/c^2} = \frac{-0.700c + \alpha c}{1 - 0.700\alpha} = -\alpha c$.

EXECUTE: $(1 - 0.700\alpha)(-\alpha) = -0.700 + \alpha$. $0.700\alpha^2 - 2\alpha + 0.700 = 0$. The quadratic formula gives $\alpha = 2.45$ or $\alpha = 0.408$. We cannot have $v > c$ so $\alpha = 0.408$. Each proton has speed $0.408c$ in the earth frame.

EVALUATE: To the earth observer, the protons are separating at $2(0.408c) = 0.816c$, but to the protons they are separating at $0.700c$.

37.55. **IDENTIFY:** We are investigating the effect of motion on a magnetic field.

SET UP and **EXECUTE:** **(a)** We want the magnetic moment. $\vec{\mu} = IA\hat{\boldsymbol{j}} = IHL\hat{\boldsymbol{j}}$.

(b) We want the torque. $\vec{\tau} = \vec{\mu}\times\vec{B} = IHLB\hat{\boldsymbol{i}}$

(c) We want $\vec{\mu}'$. $\vec{\mu}' = IHL'\hat{\boldsymbol{j}}$. $L' = L/\gamma$, so $\vec{\mu}' = (IHL/\gamma)\hat{\boldsymbol{j}} = \vec{\mu}/\gamma$.

(d) We want $\vec{\boldsymbol{B}}'$. Given that the torques are equal in both frames, we have $\vec{\mu}'\times\vec{B}' = \vec{\mu}\times\vec{B}$. Using our result from part (c) gives $(\vec{\mu}/\gamma)\times\vec{B}' = \vec{\mu}\times\vec{B}$, so $\vec{\boldsymbol{B}}' = \vec{\boldsymbol{B}}\gamma$, which we can express as $\vec{\boldsymbol{B}}' = B\gamma\hat{\boldsymbol{k}}$.

(e) Generalize from $\vec{\boldsymbol{B}}' = \vec{\boldsymbol{B}}\gamma$, which gives $\vec{\boldsymbol{B}}'_\perp = \vec{\boldsymbol{B}}_\perp\gamma$.

EVALUATE: Note that the fields are different when observed from moving reference frames.

37.56. **IDENTIFY:** We are investigating the effect of motion on an electric field.

SET UP and **EXECUTE:** **(a)** The net force is zero because there is no motion.

(b) We want $\vec{\boldsymbol{B}}'$. Using the result of problem 37.55, but with $\vec{\boldsymbol{B}} = -B\,\hat{\boldsymbol{j}}$ instead of $\vec{\boldsymbol{B}} = B\,\hat{\boldsymbol{k}}$. This gives $\vec{\boldsymbol{B}}' = \vec{\boldsymbol{B}}\gamma = -\gamma B\hat{\boldsymbol{j}}$.

(c) We want $\vec{\boldsymbol{F}}'$. Use $\vec{\boldsymbol{F}}' = Q\vec{\boldsymbol{v}}'\times\vec{\boldsymbol{B}}'$ with $\vec{\boldsymbol{v}}' = -v\hat{\boldsymbol{i}}$ and $\vec{\boldsymbol{B}}' = -\gamma B\hat{\boldsymbol{j}}$, giving $\vec{\boldsymbol{F}}' = Q\gamma vB\hat{\boldsymbol{k}}$.

(d) Generalize: $\vec{\boldsymbol{F}}' = Q\vec{E}'_\perp = Q\gamma\vec{\boldsymbol{v}}\times\vec{\boldsymbol{B}}$, so $\vec{\boldsymbol{E}}'_\perp = \gamma\vec{\boldsymbol{v}}\times\vec{\boldsymbol{B}}$.

EVALUATE: Note that there is no electric field in the lab, but there is one in the moving frame.

37.57. **IDENTIFY** and **SET UP:** An increase in wavelength corresponds to a decrease in frequency ($f = c/\lambda$), so the atoms are moving away from the earth. The galaxy is receding, so we use $f = \sqrt{\frac{c-u}{c+u}}f_0$.

EXECUTE: Solve for u: $(f/f_0)^2(c+u) = c - u$ and $u = c\left(\frac{1-(f/f_0)^2}{1+(f/f_0)^2}\right)$.

$f = c/\lambda$, $f_0 = c/\lambda_0$ so $f/f_0 = \lambda_0/\lambda$.

$$u = c\left(\frac{1-(\lambda_0/\lambda)^2}{1+(\lambda_0/\lambda)^2}\right) = c\left(\frac{1-(656.3/953.4)^2}{1+(656.3/953.4)^2}\right) = 0.357c = 1.07\times10^8 \text{ m/s}.$$

EVALUATE: The relative speed is large, 36% of c. The cosmological implication of such observations will be discussed in Chapter 44.

37.58. **IDENTIFY:** Apply the Lorentz coordinate transformation.

SET UP: Let t and t' be time intervals between the events as measured in the two frames and let x and x' be the difference in the positions of the two events as measured in the two frames.

EXECUTE: Setting $x = 0$ in the Lorentz transformation equations, the first equation becomes $x' = -\gamma ut$ and the last, upon multiplication by c, becomes $ct' = \gamma ct$. Squaring and subtracting gives $c^2t'^2 - x'^2 = \gamma^2 t^2(c^2 - u^2)$. But $\gamma^2 = c^2/(c^2 - v^2)$, so $\gamma^2 t^2(c^2 - v^2) = c^2t^2$. Therefore, $c^2t'^2 - x'^2 = c^2t^2$ which gives $x' = c\sqrt{t'^2 - t^2} = c\sqrt{(2.15 \text{ s})^2 - (1.80 \text{ s})^2} = 3.53\times10^8$ m.

EVALUATE: We did not have to calculate the speed u of frame S' relative to frame S.

37.59. **IDENTIFY:** The baseball is moving toward the radar gun, so apply the Doppler effect equation $f = \sqrt{\frac{c+u}{c-u}} f_0$.

SET UP: The baseball had better be moving nonrelativistically, so the Doppler shift formula becomes $f \cong f_0(1-(u/c))$. In the baseball's frame, this is the frequency with which the radar waves strike the baseball, and the baseball reradiates at f. But in the coach's frame, the reflected waves are Doppler shifted again, so the detected frequency is $f(1-(u/c)) = f_0(1-(u/c))^2 \approx f_0(1-2(u/c))$.

EXECUTE: $\Delta f = 2f_0(u/c)$ and the fractional frequency shift is $\frac{\Delta f}{f_0} = 2(u/c)$.

$$u = \frac{\Delta f}{2f_0}c = \frac{(2.86\times10^{-7})}{2}(3.00\times10^8 \text{ m}) = 42.9 \text{ m/s} = 154 \text{ km/h} = 92.5 \text{ mi/h}.$$

EVALUATE: $u << c$, so using the approximate expression in place of $f = \sqrt{\frac{c+u}{c-u}} f_0$ is very accurate.

37.60. **IDENTIFY:** Apply the relativistic expressions for kinetic energy, velocity transformation, length contraction and time dilation.

SET UP: In part (c) let S' be the earth frame and let S be the frame of the ball. Let the direction from Einstein to Lorentz be positive, so $u = -1.80\times10^8$ m/s. In part (d) the proper length is $l_0 = 20.0$ m and in part (f) the proper time is measured by the rabbit.

EXECUTE: **(a)** 80.0 m/s is nonrelativistic, and $K = \frac{1}{2}mv^2 = 186$ J.

(b) $K = (\gamma - 1)mc^2 = 1.31\times10^{15}$ J.

(c) In Eq. (37.23), $v' = 2.20\times10^8$ m/s, $u = -1.80\times10^8$ m/s, and so $v = 7.14\times10^7$ m/s.

(d) $l = \frac{l_0}{\gamma} = \frac{20.0 \text{ m}}{\gamma} = 13.6$ m.

(e) $\frac{20.0 \text{ m}}{2.20\times10^8 \text{ m/s}} = 9.09\times10^{-8}$ s.

(f) $\Delta t_0 = \frac{\Delta t}{\gamma} = 6.18\times10^{-8}$ s.

EVALUATE: In part (f) we could also calculate Δt_0 as $\Delta t_0 = \frac{13.6 \text{ m}}{2.20\times10^8 \text{ m/s}} = 6.18\times10^{-8}$ s.

37.61. **IDENTIFY:** We need to use the relativistic form of Newton's second law because the speed of the proton is close to the speed of light.

SET UP: $\vec{F}$ and $\vec{v}$ are perpendicular, so $F = \gamma ma = \gamma m\dfrac{v^2}{R}$. $\gamma = \dfrac{1}{\sqrt{1-v^2/c^2}} = \dfrac{1}{\sqrt{1-(0.750)^2}} = 1.512.$

EXECUTE: $F = (1.512)(1.67\times10^{-27}\ \text{kg})\dfrac{[(0.750)(3.00\times10^{8}\ \text{m/s}]^2}{628\ \text{m}} = 2.04\times10^{-13}\ \text{N}.$

EVALUATE: If we ignored relativity, the force would be

$F_{\text{rel}}/\gamma = \dfrac{2.04\times10^{-13}\ \text{N}}{1.512} = 1.35\times10^{-13}\ \text{N},$ which is substantially less than the relativistic force.

37.62. **IDENTIFY** and **SET UP:** For part (a) follow the procedure specified in the hint. For part (b) apply $f = \sqrt{\dfrac{c+u}{c-u}}f_0$ and $f = \sqrt{\dfrac{c-u}{c+u}}f_0$.

EXECUTE: **(a)** As in the hint, both the sender and the receiver measure the same distance. However, in our frame, the ship has moved between emission of successive wavefronts, and we can use the time $T = 1/f$ as the proper time, with the result that $f = \gamma f_0 > f_0$.

(b) Toward: $f_1 = f_0\sqrt{\dfrac{c+u}{c-u}} = 345\ \text{MHz}\left(\dfrac{1+0.758}{1-0.758}\right)^{1/2} = 930\ \text{MHz}$ and

$f_1 - f_0 = 930\ \text{MHz} - 345\ \text{MHz} = 585\ \text{MHz}.$

Away: $f_2 = f_0\sqrt{\dfrac{c-u}{c+u}} = 345\ \text{MHz}\left(\dfrac{1-0.758}{1+0.758}\right)^{1/2} = 128\ \text{MHz}$ and $f_2 - f_0 = -217\ \text{MHz}.$

(c) $f_3 = \gamma f_0 = 1.53 f_0 = 528\ \text{MHz},\ f_3 - f_0 = 183\ \text{MHz}.$

EVALUATE: The frequency in part (c) is the average of the two frequencies in part (b). A little algebra shows that f_3 is precisely equal to $(f_1 + f_2)/2$.

37.63. **IDENTIFY** and **SET UP:** The equation $\Delta t = \dfrac{\Delta t_0}{\sqrt{1-u^2/c^2}}$ relates the time interval in the laboratory (Δt) to the time interval (Δt_0) in the rest frame of the particle.

EXECUTE: **(a)** Solve the above equation for $(\Delta t)^2$. Squaring gives $(\Delta t)^2 = (\Delta t_0)^2(1-u^2/c^2)^{-1}$. Therefore a graph of $(\Delta t)^2$ versus $(1-u^2/c^2)^{-1}$ should be a straight line with slope equal to $(\Delta t_0)^2$. Figure 37.63 shows this graph for the data in the problem. The slope of the best-fit straight line is $0.6709\times 10^{-15}\ \text{s}^2$, so $\Delta t_0 = \sqrt{0.6709\times10^{-15}\ \text{s}^2} = 2.6\times10^{-8}\ \text{s} = 26\ \text{ns}.$

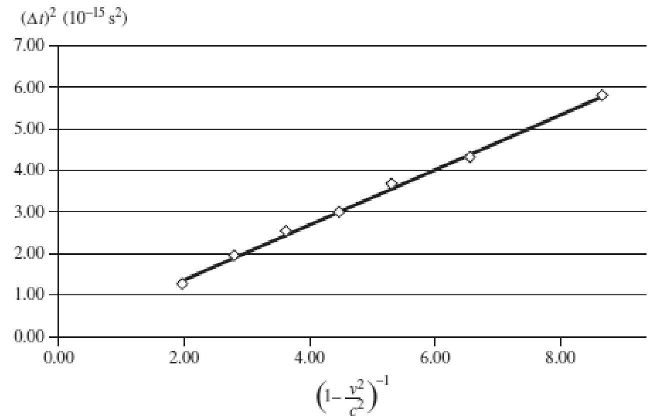

Figure 37.63

(b) Using $\Delta t = 4\,\Delta t_0$, the equation $\Delta t = \dfrac{\Delta t_0}{\sqrt{1-u^2/c^2}}$ gives $4\Delta t_0 = \dfrac{\Delta t_0}{\sqrt{1-u^2/c^2}}$. Solving for u/c gives $u/c = 0.97$.

EVALUATE: At speeds near the speed of light, there is a very large difference between the lifetime measured in the laboratory frame compared to the lifetime in the rest frame of the particle.

37.64. **IDENTIFY:** Apply the Lorentz velocity transformation.

SET UP: Let the tank and the light both be traveling in the $+x$-direction. Let S be the lab frame and let S' be the frame of the tank of water.

EXECUTE: In the equation $v_x = \dfrac{v'_x + u}{1 + uv'_x/c^2}$, $u = V$, $v' = (c/n)$. $v = \dfrac{(c/n)+V}{1+\dfrac{cV}{nc^2}} = \dfrac{(c/n)+V}{1+(V/nc)}$. For $V << c$,

$(1+V/nc)^{-1} \approx (1-V/nc)$. This gives

$v \approx [(c/n)+V][1-(V/nc)] = c/n + V - (V/n^2) - (V^2/nc) \approx \dfrac{c}{n} + \left(1-\dfrac{1}{n^2}\right)V$, so $k = \left(1-\dfrac{1}{n^2}\right)$. For water, $n = 1.333$ and $k = 0.437$.

EVALUATE: The Lorentz transformation predicts a value of k in excellent agreement with the value that is measured experimentally.

37.65. **IDENTIFY** and **SET UP:** When the force on a particle is along the same line as its velocity, the force and acceleration are related by $F = \gamma^3 ma$, where $\gamma = 1/\sqrt{1-v^2/c^2}$.

EXECUTE: **(a)** Solve the equation $F = \gamma^3 ma$ for a^2.

$$a = \frac{F}{m\gamma^3} = \frac{F}{m}\left(1-\frac{v^2}{c^2}\right)^{3/2} \qquad \rightarrow \qquad a^2 = \left(\frac{F}{m}\right)^2\left(1-\frac{v^2}{c^2}\right)^3.$$

From this result we see that a graph of a^2 versus $\left(1-\dfrac{v^2}{c^2}\right)^3$ should be a straight line with slope equal to $(F/m)^2$. Figure 37.65 shows the graph of the data in the table with the problem. It is well fit by a straight line having slope equal to 1.608×10^9 m^2/s^4. Therefore the mass is

$$(F/m)^2 = \text{slope} \qquad \rightarrow \qquad m = \frac{F}{\sqrt{\text{slope}}} = \frac{8.00\times10^{-14}\ \text{N}}{\sqrt{1.608\times10^9\ \text{m}^2/\text{s}^4}} = 2.0\times10^{-18}\ \text{kg}.$$

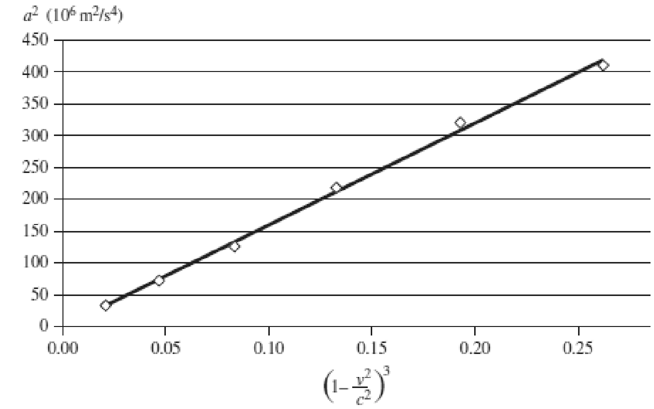

Figure 37.65

(b) In this case, $v << c$, so γ is essentially equal to 1. Therefore we can use the familiar form of Newton's second law, $F = ma$.

$a = F/m = (8.00\times10^{-14}\text{ N})/(2.0\times10^{-18}\text{ kg}) = 4.0\times10^4\text{ m/s}^2$.

EVALUATE: When v is close to c, $a = F/m$ does not give the correct result. For example, using data from the table in the problem, when $v/c = 0.85$, the acceleration is measured to be 5900 m/s^2. But using the familiar Newtonian formula we get $a = F/m = (8.00\times10^{-14}\text{ N})/(2.0\times10^{-18}\text{ kg}) = 4.0\times10^4\text{ m/s}^2$ = 40,000 m/s^2, which is *very* different from the relativistic result of 5900 m/s^2.

37.66. **IDENTIFY:** Relative motion between the observer and the source of electromagnetic waves affects the frequency received by the observer due to the Doppler effect. If the source is moving toward the observer with speed u and emitting frequency f_0, the frequency f that the observer receives is given by $f = f_0\sqrt{\dfrac{c+u}{c-u}}$, and if it is moving away the formula is $f = f_0\sqrt{\dfrac{c-u}{c+u}}$. Notice that $f > f_0$.

SET UP: In this case, we know f and f_0 and want to find u. Looking at the data given in the problem, we see that $f < f_0$, which means that the source must be moving *away from* the observer, so we use $f = f_0\sqrt{\dfrac{c-u}{c+u}}$. Solve the equation $f = f_0\sqrt{\dfrac{c-u}{c+u}}$ for u, since we know the frequencies. This gives $u = \left(\dfrac{f_0^2 - f^2}{f_0^2 + f^2}\right)c$.

EXECUTE: **(a)** To see which source is moving fastest, look at f_0/f; the larger this ratio, the greater the speed u.

For A: $f_0/f = 9.2/7.1 = 1.30$.
For B: $f_0/f = 8.6/5.4 = 1.59$.
For C: $f_0/f = 7.9/6.1 = 1.30$.
For D: $f_0/f = 8.9/8.1 = 1.10$.

Therefore source B is moving fastest and source D is moving slowest. The speed of B is

$$u = \left(\frac{(8.6\text{ THz})^2 - (5.4\text{ THz})^2}{(8.6\text{ THz})^2 + (5.4\text{ THz})^2}\right)c = 0.434c,$$ which rounds to $0.43c$, away from the detector.

(b) The speed for source D is $u = \left(\dfrac{(8.9\text{ THz})^2 - (8.1\text{ THz})^2}{(8.9\text{ THz})^2 + (8.1\text{ THz})^2}\right)c = 0.094c$, away from the detector.

(c) Since B is now approaching the detector, we use $f = f_0\sqrt{\dfrac{c+u}{c-u}}$ with $u = 0.434c$ and $f_0 = 8.6$ THz.

This gives $f = f_0\sqrt{\dfrac{c+u}{c-u}} = (8.6\text{ THz})\sqrt{\dfrac{1+0.434}{1-0.434}} = 14\text{ THz} = 1.4\times10^{13}$ Hz.

EVALUATE: The change in observed frequency is small for low speeds but increases dramatically as $u \to c$.

37.67. **IDENTIFY:** We are using the Lorentz transformation equations to investigate space-time diagrams.
SET UP: S is the reference frame of the train station and S' is the moving frame of the rocket train. $x' = \gamma(x - vt)$, $t' = \gamma\left(t - xv/c^2\right)$.

EXECUTE: **(a)** Event 1: $x_1 = 0$, $t_1 = 0$, so $x_1' = 0$, $t_1' = 0$. So $(x_1', t_1') = (0, 0)$.

Event 2: $x_2 = -L$, $t_2 = 0$. $x_2' = -L\gamma$, $t_2' = [-(-L)v/c^2]\gamma = Lv\gamma/c^2$. So $(x_2', t_2') = (-L\gamma, Lv\gamma/c^2)$.

Event 3: $x_3 = 0$, $t_3 = T$. $x_3' = -vT\gamma$, $t_3' = T\gamma$. So $(x_3', t_3') = (-vT\gamma, T\gamma)$.

Event 4: $x_4 = -L$, $t_4 = T$. $x_4' = -(L + vT)\gamma$, $t_4' = (T + Lv/c^2)\gamma$. So $(x_4', t_4') = \left((-L + vT)\gamma, (T + Lv/c^2)\gamma\right)$.

(b) Fig. 37.67 shows the spacetime diagram.

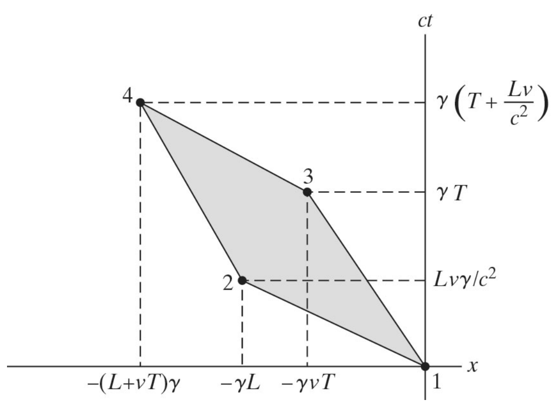

Figure 37.67

(c) We want the area in frame S. $A = LcT = cLT$.
(d) We want the area in frame S'. Use the hint in the problem. For two vectors in the xy-plane, the cross product has a z component given by $A_xB_y - B_xA_y$, so the magnitude of this quantity is the area of the parellelogram. Apply this approach to the diagram in Fig. 37.67. $\vec{A}$ is the vector from 1 to 3 and $\vec{B}$ is the vector from 1 to 2. Their components are $A_x = -\gamma vt$, $A_y = \gamma T$, $B_x = -\gamma L$, and $B_y = Lv\gamma/c^2$. The area is $A = |A_xB_y - B_xA_y| = LT$. But recall that we replace t with ct, so $T \to cT$. Therefore the area is $A = cLT$.
EVALUATE: **(e)** The area is cLT in both reference frames. So it is independent of the reference frame, or "Lorentz invariant."

37.68. **IDENTIFY:** Apply the Doppler effect equation.
SET UP: At the two positions shown in the figure given in the problem, the velocities of the star relative to the earth are $u + v$ and $u - v$, where u is the velocity of the center of mass and v is the orbital velocity.
EXECUTE: **(a)** $f_0 = 4.568110\times10^{14}$ Hz; $f_+ = 4.568910\times10^{14}$ Hz; $f_- = 4.567710\times10^{14}$ Hz.

$$\left.\begin{aligned} f_+ &= \sqrt{\frac{c+(u+v)}{c-(u+v)}}f_0 \\ f_- &= \sqrt{\frac{c+(u-v)}{c-(u-v)}}f_0 \end{aligned}\right\} \Rightarrow \begin{aligned} &f_+^2(c-(u+v)) = f_0^2\,(c+(u+v)) \\ &f_-^2(c-(u-v)) = f_0^2(c+(u-v)) \end{aligned}$$

$(u+v) = \dfrac{(f_+/f_0)^2-1}{(f_+/f_0)^2+1}c$ and $(u-v) = \dfrac{(f_-^2/f_0^2)-1}{(f_-^2/f_0^2)+1}c$. $u+v = 5.25\times10^4$ m/s and $u-v = -2.63\times10^4$ m/s.

This gives $u = +1.31\times10^4$ m/s (moving toward at 13.1 km/s) and $v = 3.94\times10^4$ m/s.

(b) $v = 3.94\times10^4$ m/s; $T = 11.0$ days. $2\pi R = vt \Rightarrow$

$R = \dfrac{(3.94\times10^4\text{ m/s})(11.0\text{ days})(24\text{ hrs/day})(3600\text{ sec/hr})}{2\pi} = 5.96\times10^9$ m. This is about 0.040 times the earth-sun distance.

Also the gravitational force between them (a distance of $2R$) must equal the centripetal force from the center of mass:

$$\frac{(Gm^2)}{(2R)^2} = \frac{mv^2}{R} \Rightarrow m = \frac{4Rv^2}{G} = \frac{4(5.96\times10^9\text{ m})(3.94\times10^4\text{ m/s})^2}{6.672\times10^{-11}\text{ N}\cdot\text{m}^2/\text{kg}^2} = 5.55\times10^{29}\text{ kg} = 0.279\,m_{\text{sun}}.$$

EVALUATE: u and v are both much less than c, so we could have used the approximate expression $\Delta f = \pm f_0 v_{\text{rev}}/c$, where v_{rev} is the speed of the source relative to the observer.

37.69. IDENTIFY: Apply conservation of total energy, in the frame in which the total momentum is zero (the center of momentum frame).

SET UP: In the center of momentum frame, the two protons approach each other with equal velocities (since the protons have the same mass). After the collision, the two protons are at rest—but now there are kaons as well. In this situation the kinetic energy of the protons must equal the total rest energy of the two kaons.

EXECUTE: **(a)** $2(\gamma_{\text{cm}}-1)m_{\text{p}}c^2 = 2m_{\text{k}}c^2 \Rightarrow \gamma_{\text{cm}} = 1+\dfrac{m_{\text{k}}}{m_{\text{p}}} = 1.526.$ The velocity of a proton in the center of momentum frame is then $v_{\text{cm}} = c\sqrt{\dfrac{\gamma_{\text{cm}}^2-1}{\gamma_{\text{cm}}^2}} = 0.7554c.$

To get the velocity of this proton in the lab frame, we must use the Lorentz velocity transformations. This is the same as "hopping" into the proton that will be our target and asking what the velocity of the projectile proton is. Taking the lab frame to be the unprimed frame moving to the left, $u = v_{\text{cm}}$ and $v' = v_{\text{cm}}$ (the velocity of the projectile proton in the center of momentum frame).

$$v_{\text{lab}} = \frac{v'+u}{1+\frac{uv'}{c^2}} = \frac{2v_{\text{cm}}}{1+\frac{v_{\text{cm}}^2}{c^2}} = 0.9619c \Rightarrow \gamma_{\text{lab}} = \frac{1}{\sqrt{1-\frac{v_{\text{lab}}^2}{c^2}}} = 3.658 \Rightarrow K_{\text{lab}} = (\gamma_{\text{lab}}-1)m_{\text{p}}c^2 = 2494\text{ MeV}.$$

(b) $\dfrac{K_{\text{lab}}}{2m_{\text{k}}} = \dfrac{2494\text{ MeV}}{2(493.7\text{ MeV})} = 2.526.$

(c) The center of momentum case considered in part (a) is the same as this situation. Thus, the kinetic energy required *is* just twice the rest mass energy of the kaons. $K_{\text{cm}} = 2(493.7\text{ MeV}) = 987.4\text{ MeV}.$

EVALUATE: The colliding beam situation of part (c) offers a substantial advantage over the fixed target experiment in part (b). It takes less energy to create two kaons in the proton center of momentum frame.

37.70. IDENTIFY and **SET UP:** Apply the procedures specified in the problem.

EXECUTE: For any function $f = f(x,t)$ and $x = x(x',t'), t = t(x',t')$, let $F(x',t') = f(x(x',t'),t(x',t'))$ and use the standard (but mathematically improper) notation $F(x',t') = f(x',t')$. The chain rule is then

$$\frac{\partial f(x',t')}{\partial x}=\frac{\partial f(x,t)}{\partial x'}\frac{\partial x'}{\partial x}+\frac{\partial f(x',t')}{\partial t'}\frac{\partial t'}{\partial x},$$
$$\frac{\partial f(x',t')}{\partial t}=\frac{\partial f(x,t)}{\partial x'}\frac{\partial x'}{\partial t}+\frac{\partial f(x',t')}{\partial x'}\frac{\partial t'}{\partial t}.$$

In this solution, the explicit dependence of the functions on the sets of dependent variables is suppressed, and the above relations are then $\frac{\partial f}{\partial x}=\frac{\partial f}{\partial x'}\frac{\partial x'}{\partial x}+\frac{\partial f}{\partial t'}\frac{\partial t'}{\partial x}$, $\frac{\partial f}{\partial t}=\frac{\partial f}{\partial x'}\frac{\partial x'}{\partial t}+\frac{\partial f}{\partial t'}\frac{\partial t'}{\partial t}$.

(a) $\frac{\partial x'}{\partial x}=1, \frac{\partial x'}{\partial t}=-v, \frac{\partial t'}{\partial x}=0$ and $\frac{\partial t'}{\partial t}=1$. Then, $\frac{\partial E}{\partial x}=\frac{\partial E}{\partial x'}$, and $\frac{\partial^2 E}{\partial x^2}=\frac{\partial^2 E}{\partial x'^2}$. For the time derivative, $\frac{\partial E}{\partial t}=-v\frac{\partial E}{\partial x'}+\frac{\partial E}{\partial t'}$. To find the second time derivative, the chain rule must be applied to both terms; that is, $\frac{\partial}{\partial t}\frac{\partial E}{\partial x'}=-v\frac{\partial^2 E}{\partial x'^2}+\frac{\partial^2 E}{\partial t'\partial x'}, \frac{\partial}{\partial t}\frac{\partial E}{\partial t'}=-v\frac{\partial^2 E}{\partial x'\partial t'}+\frac{\partial^2 E}{\partial t'^2}$.

Using these in $\frac{\partial^2 E}{\partial t^2}$, collecting terms and equating the mixed partial derivatives gives

$\frac{\partial^2 E}{\partial t^2}=v^2\frac{\partial^2 E}{\partial x'^2}-2v\frac{\partial^2 E}{\partial x'\partial t'}+\frac{\partial^2 E}{\partial t'^2}$, and using this and the above expression for $\frac{\partial^2 E}{\partial x'^2}$ gives the result.

(b) For the Lorentz transformation, $\frac{\partial x'}{\partial x}=\gamma, \frac{\partial x'}{\partial t}=\gamma v, \frac{\partial t'}{\partial x}=\gamma v/c^2$ and $\frac{\partial t'}{\partial t}=\gamma$.

The first partials are then $\frac{\partial E}{\partial x}=\gamma\frac{\partial E}{\partial x'}-\gamma\frac{v}{c^2}\frac{\partial E}{\partial t'}, \frac{\partial E}{\partial t}=-\gamma v\frac{\partial E}{\partial x'}+\gamma\frac{\partial E}{\partial t'}$

and the second partials are (again equating the mixed partials)

$$\frac{\partial^2 E}{\partial x^2}=\gamma^2\frac{\partial^2 E}{\partial x'^2}+\gamma^2\frac{v^2}{c^4}\frac{\partial^2 E}{\partial t'^2}-2\gamma^2\frac{v}{c^2}\frac{\partial^2 E}{\partial x'\partial t'}$$
$$\frac{\partial^2 E}{\partial t^2}=\gamma^2 v^2\frac{\partial^2 E}{\partial x'^2}+\gamma^2\frac{\partial^2 E}{\partial t'^2}-2\gamma^2 v\frac{\partial^2 E}{\partial x'\partial t'}.$$

Substituting into the wave equation and combining terms (note that the mixed partials cancel),

$$\frac{\partial^2 E}{\partial x^2}-\frac{1}{c^2}\frac{\partial^2 E}{\partial t^2}=\gamma^2\left(1-\frac{v^2}{c^2}\right)\frac{\partial^2 E}{\partial x'^2}+\gamma^2\left(\frac{v^2}{c^4}-\frac{1}{c^2}\right)\frac{\partial^2 E}{\partial t'^2}=\frac{\partial^2 E}{\partial x'^2}-\frac{1}{c^2}\frac{\partial^2 E}{\partial t'^2}=0.$$

EVALUATE: The general form of the wave equation is given by Eq. (32.1). The coefficient of the $\partial^2/\partial t^2$ term is the inverse of the square of the wave speed. This coefficient is the same in both frames, so the wave speed is the same in both frames.

37.71. **IDENTIFY** and **SET UP:** The relativity formulas apply, but c = 300 m/s in this universe.
$\gamma=1/\sqrt{1-v^2/c^2}$ = $1/\sqrt{1-(180\text{ m/s})^2/(300\text{ m/s})^2}$ = 1.25. The length is $l = l_0/\gamma$.

EXECUTE: $l = l_0/\gamma$ = (60 m)/(1.25) = 48 m, choice (c).

EVALUATE: Relativistic effects would be "common sense" in this universe!

37.72. **IDENTIFY** and **SET UP:** The relativity formulas apply, but c = 300 m/s in this universe.
$\gamma=1/\sqrt{1-v^2/c^2}$ = $1/\sqrt{1-(180\text{ m/s})^2/(300\text{ m/s})^2}$ = 1.40.

EXECUTE: The relativistic mass is $m\gamma$ = (20,000 kg)(1.25) = 25,000 kg, choice (d).

EVALUATE: The relativistic mass of the passengers and their luggage would also be greater by the factor 1.25, so excess baggage fees could be rather common.

37.73. **IDENTIFY:** The rest energy is $E_0 = mc^2$.

SET UP: In our universe, $E_0 = mc^2$ and in the alternative universe the same formula would apply, except that c would be different, call it c', so $E_0' = mc'^2$. Therefore $E_0' = \left(\frac{E_0}{c^2}\right)c'^2$.

EXECUTE: $E_0' = \left(\frac{E_0}{c^2}\right)c'^2 = \left(\frac{8.2\times10^{-14}\text{ J}}{(3.0\times10^8\text{ m/s})^2}\right)(300\text{ m/s})^2 = 8.2\times10^{-26}\text{ J}$, choice (b).

EVALUATE: The rest energy of all other particles would be reduced by the same fraction in this alternate universe.

37.74. **IDENTIFY** and **SET UP:** The kinetic energy is $K = (\gamma - 1)mc^2$.

EXECUTE: The kinetic energy is now equal to the rest energy, so $K = (\gamma - 1)mc^2 = mc^2$, which means that $\gamma = 2$. Therefore $2 = 1/\sqrt{1 - v^2/c^2}$. Solving for v gives $v = c\sqrt{1-(1/2)^2} = (300\text{ m/s})\sqrt{3/4} = 260\text{ m/s}$, choice (b).

EVALUATE: Airplanes and rockets would certainly need to take relativistic effects into consideration in this alternative universe!

38

PHOTONS: LIGHT WAVES BEHAVING AS PARTICLES

VP38.3.1. **IDENTIFY:** This problem involves the energy and momentum of a photon.
SET UP: $E = hc/\lambda$, $\lambda = h/p$.
EXECUTE: **(a)** We want the energy and momentum of the photon. $E = hc/\lambda = hc/(625\text{ nm}) = 3.18 \times 10^{-19}$ J. $p = h/\lambda = h/(625\text{ nm}) = 1.06\times10^{-27}\text{ kg}\cdot\text{m/s}$.
(b) We want the power output of the laser. $\dfrac{E}{t} = \dfrac{(2.15\times10^{16}\text{photons})(3.18\times10^{-19}\text{ J/photon})}{1.00\text{ s}}$ $= 6.77$ mW.
EVALUATE: Don't confuse the frequency of the light with the frequency at which photons are emitted. They are *very* different!

VP38.3.2. **IDENTIFY:** This problem is about the photoelectric effect.
SET UP: $hf = K_{max} + \phi$.
EXECUTE: **(a)** We want the minimum frequency to produced photoelectrons. This is the threshold frequency, at which the kinetic energy is zero, so $hf = \phi$. $f = \phi/h = (4.55\text{ eV})/h = 1.10\times10^{15}$ Hz.
(b) We want the frequency when the maximum kinetic energy is 1.53 eV. Solve $hf = K_{max} + \phi$ for f, giving

$$f = \frac{K_{max} + \phi}{h} = \frac{1.53\text{ eV} + 4.55\text{ eV}}{h} = 1.47\times10^{15}\text{ Hz}.$$

EVALUATE: Be prepared to use h in units of either $\text{J}\cdot\text{s}$ or $\text{eV}\cdot\text{s}$, depending on the given units. Doing so can avoid tedious unit conversions.

VP38.3.3. **IDENTIFY:** This problem is about the photoelectric effect.
SET UP: $eV_0 = hc/\lambda - \phi$, $f\lambda = c$.
EXECUTE: **(a)** We want the work function. Solve $eV_0 = hc/\lambda - \phi$ for ϕ using $V_0 = 1.37$ V and $\lambda = 475$ nm, giving $\phi = 1.24$ eV.
(b) We want V_0 if $\lambda = 425$ nm. Solve $eV_0 = hc/\lambda - \phi$ for V_0 using $\phi = 1.24$ eV and $\lambda = 425$ nm. This gives $V_0 = 1.68$ eV.
EVALUATE: Decreasing the photon wavelength increases its energy, so the stopping potential increases. From Table 38.1 we see that the ϕ we found is around half that of sodium, so it is a reasonable value.

VP38.3.4. **IDENTIFY:** This problem is about the photoelectric effect.
SET UP: $E = hc/\lambda$.
EXECUTE: **(a)** We want the kinetic energy in eV. Using $K = \frac{1}{2}mv^2$, with m the electron mass and $v = 6.95 \times 10^5$ m/s gives $K = 2.20 \times 10^{-19}$ J = 1.37 eV.

(b) We want the photon energy. $E = hc/\lambda = hc/(306\text{ nm}) = 4.05\text{ eV}$.

(c) We want ϕ. $E_{\text{photon}} = K_{\text{max}} + \phi$. $\phi = 4.05\text{ eV} - 1.37\text{ eV} = 2.68\text{ eV}$.

EVALUATE: The work function is about the same as for sodium, so it is reasonable.

VP38.6.1. **IDENTIFY:** We are dealing with Compton scattering.

SET UP: $\lambda' - \lambda = \dfrac{h}{mc}(1 - \cos\phi)$. We want the increase in the wavelength.

EXECUTE: **(a)** $\lambda' - \lambda = \dfrac{h}{mc}(1-\cos\phi) = \left(2.426\times10^{-12}\text{ m}\right)\left(1-\cos 14.5°\right) = 7.73\times10^{5}\text{ nm}$.

(b) $\dfrac{\lambda' - \lambda}{\lambda} = \dfrac{7.73\times10^{5}\text{ nm}}{0.251\text{ nm}} = 0.0308\%$.

EVALUATE: The fractional change in the wavelength is very small. It would be larger if the scattering angle ϕ were closer to 180°.

VP38.6.2. **IDENTIFY:** We are dealing with Compton scattering.

SET UP: $\lambda' - \lambda = \dfrac{h}{mc}(1-\cos\phi)$, $f\lambda = c$. We want the frequency of the scattered waves. Using $f\lambda = c$ gives

$$\frac{1}{f'} = \frac{1}{f} + \frac{h}{mc^2}(1-\cos\phi).$$

EXECUTE: **(a)** $\phi = 90.00°$: Using the given frequency and scattering angle gives $f' = 1.247\times10^{18}$ Hz.

(b) $\phi = 180.0°$: Working as in (a) but with $\phi = 180.0°$ gives $f' = 1.235\times10^{18}$ Hz.

EVALUATE: For $\phi = 180°$ the x rays are scattered directly back from their original direction, but at $\phi = 90.0°$ they go off perpendicular to their original direction. Note that the frequency of the scattered waves is different in each case.

VP38.6.3. **IDENTIFY:** We are dealing with Compton scattering off of a proton.

SET UP: $\lambda' - \lambda = \dfrac{h}{mc}(1-\cos\phi)$, where m is now the mass of a *proton*. We want the scattering angle ϕ.

Solving for $\cos\phi$ gives $\cos\phi = 1 - \dfrac{mc}{h}(\lambda' - \lambda)$, with $\lambda = 2.50\times10^{-12}$ m.

EXECUTE: **(a)** $\lambda' = \lambda + 0.000100\lambda$: $\cos\phi = 1 - \dfrac{mc}{h}(\lambda' - \lambda) = \dfrac{mc}{h}(\lambda + 0.000100\lambda - \lambda)$

$= 1 - \dfrac{mc}{h}(0.000100\lambda)$.

Using the *proton* mass gives $\phi = 35.8°$.

(b) $\lambda' = \lambda + 0.000800\lambda$: $\cos\phi = 1 - \dfrac{mc}{h}(\lambda' - \lambda) = \dfrac{mc}{h}(\lambda + 0.000100\lambda - \lambda) = 1 - \dfrac{mc}{h}(0.000800\lambda)$.

$\phi = 121°$.

EVALUATE: Note that the scattering angle has a considerable effect on the wavelength of the scattered wave.

VP38.6.4. **IDENTIFY:** This problem involves the annihilation of a proton and an antiproton.

SET UP: We want the energy and wavelength of the resulting photons. $E = hc/\lambda$.

EXECUTE: **(a)** Initial kinetic energy is negligible. The energy of the two photons is equal to the rest energy of the two protons (which is 938.3 MeV each), and each photon has the same energy due to momentum conservation. Therefore $E_{\text{photon}} = 938.3$ MeV. The wavelength of each photon is $\lambda = hc/E$ $= hc/(938.3\text{ MeV}) = 1.32\times10^{-15}$ m.

(b) Initial kinetic energy of each proton is 545 MeV. In this case, the energy of the photons is equal to the rest energy of the protons plus their kinetic energy, so the energy of each photon is E_{photon} = 938.3 MeV + 545 MeV = 1483.3 MeV. $\lambda = hc/E = hc/(1483.3\text{ MeV}) = 8.36\times10^{-16}$ m.

EVALUATE: The wavelength of the photons is less when the protons have substantial energy. This is a reasonable result because short-wavelength photons have more energy than long-wavelength photons.

VP38.7.1. **IDENTIFY:** This problem involves the uncertainty principle.
SET UP: $\Delta t\Delta E = \hbar/2$, $\Delta x\Delta p_x = \hbar/2$, $\lambda = h/p$, $E = hc/\lambda$.

EXECUTE: **(a)** We want the momentum. $p = h/\lambda = h/(633\text{ nm}) = 1.05\times10^{-27}\ \text{kg}\cdot\text{m/s}$.

(b) We want the minimum uncertainty in the momentum. We know that $\Delta x = 700\times10^{-6}$ m.

$$\Delta p_{\text{min}} = \frac{\hbar}{2\Delta x} = \frac{1.055\times10^{-34}\ \text{J}\cdot\text{s}}{2(7.00\times10^{-6}\ \text{m})} = 7.54\times10^{-30}\ \text{kg}\cdot\text{m/s}.$$

The percent uncertainty is

$$\frac{\Delta p_{\text{min}}}{p_{\text{min}}} = \frac{7.54\times10^{-30}\ \text{kg}\cdot\text{m/s}}{1.05\times10^{-27}\ \text{kg}\cdot\text{m/s}} = 0.720\%.$$

(c) We want the energy. $E = hc/\lambda = hc/(633\text{ nm}) = 3.14\times10^{-19}$ J.
(d) We want the minimum uncertainty in the energy. We use $\Delta t\Delta E = \hbar/2$ where Δt is the time for the pulse to propagate 7.00×10^{-6} m. Therefore

$$\Delta t = \frac{\Delta x}{c} = \frac{7.00\times10^{-6}\ \text{m}}{c} = 2.333\times10^{-14}\ \text{s}.$$

$$\Delta E = \frac{\hbar}{2\Delta t} = \frac{h}{2\left(2.333\times10^{-14}\ \text{s}\right)} = 2.26\times10^{-21}\ \text{s}.$$

Dividing the result in (d) by the energy in (c) gives

$$\frac{\Delta E}{E} = 0.720\%.$$

EVALUATE: Note that the uncertainties in p and E are very small percents.

VP38.7.2. **IDENTIFY:** This problem involves the uncertainty principle.
SET UP: $\Delta t\Delta E = h/2$, $E = hf$, $f\lambda = c$.

EXECUTE: **(a)** We want the time Δt of the pulse.

$$\Delta t = \frac{\hbar}{2\Delta E} = \frac{\hbar}{2\left(5.50\times10^{-29}\text{J}\right)} = 9.59\times10^{-7}\ \text{s}.$$

(b) We want the length of the pulse. $L = c\Delta t = c\left(9.59\times10^{-7}\ \text{s}\right) = 288$ m.

(c) We want the energy. $E = hf = h(3.00\text{ GHz}) = 1.99\times10^{-24}$ J.

(d) We want the uncertainty in the frequency. $E = hf$, so $\Delta E = h\Delta f$. Also $\Delta E = \dfrac{h}{2\Delta t}$ $\Delta E = \dfrac{\hbar}{2\Delta t}$.

Combining gives $\dfrac{\hbar}{2\Delta t} = h\Delta f$, so

$$\Delta f = \frac{1}{4\pi\Delta t} = \frac{1}{4\pi\left(9.59\times10^{-7}\ \text{s}\right)} = 8.30\times10^{-5}\ \text{GHz}.$$

EVALUATE: As we have seen before, the fractional uncertainties arising from the uncertainty principle are usually very small.

VP38.7.3. **IDENTIFY:** This problem involves the uncertainty principle.

SET UP: $\Delta t\Delta E \ge \hbar/2$, $E = hf$, $f\lambda = c$.

EXECUTE: **(a)** We want the wavelength and frequency of the laser light. Using $E = hf$, we see that $\Delta E = h\Delta f$. We know that $\Delta E = 6.70\%E = 0.0670hf$ and that $\Delta E = 2.33 \times 10^{-20}$ J. Therefore 2.33×10^{-20} J $= 0.0670hf$, which gives $f = 5.25 \times 10^{14}$ Hz. Using this frequency, the wavelength is $\lambda = c/f = 572$ nm.

(b) We want the minimum uncertainty in f. $E = hf$, so $\Delta E = h\Delta f$. Thus

$$\Delta f = \frac{\Delta E}{h} = \frac{2.33\times10^{-20}\ \text{J}}{h} = 3.52\times10^{13}\ \text{Hz}.$$

(c) We want the time duration Δt of the pulse. Using $\Delta t\Delta E \ge \hbar/2$ gives

$$\Delta t = \frac{\hbar}{2\Delta E} = \frac{\hbar}{2(2.33\times10^{-20}\ \text{J})} = 2.26\times10^{-15}\ \text{s} = 2.26\ \text{fs}.$$

EVALUATE: As before, the fractional uncertainties are very small.

VP38.7.4. **IDENTIFY:** This problem involves the uncertainty principle.

SET UP: $\Delta t\Delta E \ge \hbar/2$, $E = hc/\lambda$. The average photon energy is 0.0155 eV, the energy of a pulse is 2.39 eV, and on the *average* there are 5.00×10^{12} photons per pulse.

EXECUTE: **(a)** We want the time duration of a pulse. As pointed out in Example 7.4, the minimum uncertainty Δt for a photon is the time duration of the pulse. Using $\Delta t\Delta E \ge \hbar/2$ gives

$$\Delta t = \frac{\hbar}{2\Delta E} = \frac{\left(4.136\times10^{-15}\ \text{eV}\cdot\text{s}\right)/2\pi}{2\left(0.0155\ \text{eV}\right)} = 2.12\times10^{-14}\ \text{s}.$$

(b) We want the wavelength. Using $E = hc/\lambda$ gives $\lambda = hc/E = hc/(2.39\ \text{eV}) = 519$ nm.

(c) We want the energy per pulse. This energy is equal to the energy per average photon times the number of photons in a pulse. Therefore $E = (2.39$ eV/photon$)(5.00 \times 10^{12}$ photons/pulse$)$ $= 1.195 \times 10^{13}$ eV $= 1.91$ μJ per pulse.

EVALUATE: The energy per pulse is small, but the pulse lasts for a very short time, so the power during the pulse is very large. Note that some of the photons have wavelengths longer than 519 and some have shorter wavelengths.

38.1. **IDENTIFY** and **SET UP:** Apply $c = f\lambda$, $p = h/\lambda$, and $E = pc$.

EXECUTE:
$$f = \frac{c}{\lambda} = \frac{3.00\times10^{8}\,\text{m/s}}{5.20\times10^{-7}\ \text{m}} = 5.77\times10^{14}\ \text{Hz}.$$

$$p = \frac{h}{\lambda} = \frac{6.63\times10^{-34}\ \text{J}\cdot\text{s}}{5.20\times10^{-7}\ \text{m}} = 1.28\times10^{-27}\ \text{kg}\cdot\text{m/s}.$$

$$E = pc = (1.28\times10^{-27}\ \text{kg}\cdot\text{m/s})\,(3.00\times10^{8}\,\text{m/s}) = 3.84\times10^{-19}\ \text{J} = 2.40\ \text{eV}.$$

EVALUATE: Visible-light photons have energies of a few eV.

38.2. **IDENTIFY** and **SET UP:** $c = f\lambda$ relates frequency and wavelength and $E = hf$ relates energy and frequency for a photon. $c = 3.00\times10^{8}$ m/s. $1\ \text{eV} = 1.60\times10^{-16}$ J.

EXECUTE: **(a)** $f = \dfrac{c}{\lambda} = \dfrac{3.00\times10^{8}\ \text{m/s}}{505\times10^{-9}\ \text{m}} = 5.94\times10^{14}\ \text{Hz}.$

(b) $E = hf = (6.626\times10^{-34}\ \text{J}\cdot\text{s})(5.94\times10^{14}\ \text{Hz}) = 3.94\times10^{-19}\ \text{J} = 2.46\ \text{eV}.$

(c) $K = \frac{1}{2}mv^2$, so $v = \sqrt{\dfrac{2K}{m}} = \sqrt{\dfrac{2(3.94\times10^{-19}\ \text{J})}{9.5\times10^{-15}\ \text{kg}}} = 9.1\ \text{mm/s}.$

EVALUATE: Compared to kinetic energies of common objects moving at typical speeds, the energy of a visible-light photon is extremely small.

38.3. **IDENTIFY** and **SET UP:** $c = f\lambda$. The source emits $(0.05)(75\text{ J}) = 3.75\text{ J}$ of energy as visible light each second. $E = hf$, with $h = 6.63\times10^{-34}\text{ J}\cdot\text{s}$.

EXECUTE: **(a)** $f = \dfrac{c}{\lambda} = \dfrac{3.00\times10^{8}\text{ m/s}}{600\times10^{-9}\text{ m}} = 5.00\times10^{14}\text{ Hz}.$

(b) $E = hf = (6.63\times10^{-34}\text{ J}\cdot\text{s})(5.00\times10^{14}\text{ Hz}) = 3.32\times10^{-19}\text{ J}.$ The number of photons emitted per second is $\dfrac{3.75\text{ J}}{3.32\times10^{-19}\text{ J/photon}} = 1.13\times10^{19}$ photons.

EVALUATE: **(c)** No. The frequency of the light depends on the energy of each photon. The number of photons emitted per second is proportional to the power output of the source.

38.4. **IDENTIFY** and **SET UP:** $P_{\text{av}} = \dfrac{\text{energy}}{t}$. $1\text{ eV} = 1.60\times10^{-19}\text{ J}$. For a photon, $E = hf = \dfrac{hc}{\lambda}$.

$$h = 6.63\times10^{-34}\text{ J}\cdot\text{s}.$$

EXECUTE: **(a)** $\text{energy} = P_{\text{av}}t = (0.600\text{ W})(20.0\times10^{-3}\text{ s}) = 1.20\times10^{-2}\text{ J} = 7.5\times10^{16}\text{ eV}.$

(b) $E = \dfrac{hc}{\lambda} = \dfrac{(6.63\times10^{-34}\text{ J}\cdot\text{s})(3.00\times10^{8}\text{ m/s})}{652\times10^{-9}\text{ m}} = 3.05\times10^{-19}\text{ J} = 1.91\text{ eV}.$

(c) The number of photons is the total energy in a pulse divided by the energy of one photon:

$$\frac{1.20\times10^{-2}\text{ J}}{3.05\times10^{-19}\text{ J/photon}} = 3.93\times10^{16}\text{ photons}.$$

EVALUATE: The number of photons in each pulse is very large.

38.5. **IDENTIFY** and **SET UP:** A photon has zero rest mass, so its energy is $E = pc$ and its momentum is $p = \dfrac{h}{\lambda}$.

EXECUTE: **(a)** $E = pc = (8.24\times10^{-28}\text{ kg}\cdot\text{m/s})(2.998\times10^{8}\text{ m/s}) = 2.47\times10^{-19}\text{ J}$
$= (2.47\times10^{-19}\text{ J})(1\text{ eV}/1.602\times10^{-19}\text{ J}) = 1.54\text{ eV}.$

(b) $p = \dfrac{h}{\lambda}$, so $\lambda = \dfrac{h}{p} = \dfrac{6.626\times10^{-34}\text{ J}\cdot\text{s}}{8.24\times10^{-28}\text{ kg}\cdot\text{m/s}} = 8.04\times10^{-7}\text{ m} = 804\text{ nm}.$

EVALUATE: This wavelength is longer than visible wavelengths; it is in the infrared region of the electromagnetic spectrum. To check our result we could verify that the same E is given by $E = hc/\lambda$, using the λ we have calculated.

38.6. **IDENTIFY** and **SET UP:** For the photoelectric effect, the maximum kinetic energy of the photoelectrons is $\frac{1}{2}mv_{\text{max}}^2 = hf - \phi = \dfrac{hc}{\lambda} - \phi$. Take the work function ϕ from Table 38.1. Solve for v_{max}. Note that we wrote f as c/λ.

EXECUTE: $\frac{1}{2}mv_{\text{max}}^2 = \dfrac{(6.626\times10^{-34}\text{ J}\cdot\text{s})(2.998\times10^{8}\text{ m/s})}{235\times10^{-9}\text{ m}} - (5.1\text{ eV})(1.602\times10^{-19}\text{ J/1 eV}).$

$$\tfrac{1}{2}mv_{\text{max}}^2 = 8.453\times10^{-19}\text{ J} - 8.170\times10^{-19}\text{ J} = 2.83\times10^{-20}\text{ J}.$$

$$v_{\text{max}} = \sqrt{\frac{2(2.83\times10^{-20}\text{ J})}{9.109\times10^{-31}\text{ kg}}} = 2.49\times10^{5}\text{ m/s}.$$

EVALUATE: The work function in eV was converted to joules for use in the equation $\frac{1}{2}mv_{\text{max}}^2 = hf - \phi = \dfrac{hc}{\lambda} - \phi$. A photon with $\lambda = 235\text{ nm}$ has energy greater then the work function for the surface.

38.7. **IDENTIFY**: The photoelectric effect occurs. The kinetic energy of the photoelectron is the difference between the initial energy of the photon and the work function of the metal.

SET UP: $\frac{1}{2}mv_{\text{max}}^2 = hf - \phi$, $E = hc/\lambda$.

EXECUTE: Use the data for the 400.0-nm light to calculate ϕ. Solving for ϕ gives $\phi = \dfrac{hc}{\lambda} - \frac{1}{2}mv_{\text{max}}^2$ $= \dfrac{(4.136\times10^{-15}\text{ eV}\cdot\text{s})(3.00\times10^{8}\text{ m/s})}{400.0\times10^{-9}\text{ m}} - 1.10\text{ eV} = 3.10\text{ eV} - 1.10\text{ eV} = 2.00\text{ eV}.$ Then for 300.0 nm, we have $\frac{1}{2}mv_{\text{max}}^2 = hf - \phi = \dfrac{hc}{\lambda} - \phi = \dfrac{(4.136\times10^{-15}\text{ eV}\cdot\text{s})(3.00\times10^{8}\text{ m/s})}{300.0\times10^{-9}\text{ m}} - 2.00\text{ eV},$ which gives $\frac{1}{2}mv_{\text{max}}^2 = 4.14\text{ eV} - 2.00\text{ eV} = 2.14\text{ eV}.$

EVALUATE: When the wavelength decreases the energy of the photons increases and the photoelectrons have a larger minimum kinetic energy.

38.8. **IDENTIFY** and **SET UP:** $eV_0 = \frac{1}{2}mv_{\text{max}}^2$, where V_0 is the stopping potential. The stopping potential in volts equals eV_0 in electron volts. $\frac{1}{2}mv_{\text{max}}^2 = hf - \phi$ and $f = c/\lambda$.

EXECUTE: **(a)** $eV_0 = \frac{1}{2}mv_{\text{max}}^2$, so $eV_0 = hf - \phi = \dfrac{(4.136\times10^{-15}\text{ eV}\cdot\text{s})(3.00\times10^{8}\text{ m/s})}{190\times10^{-9}\text{ m}} - 2.3\text{ eV}$ $= 6.53\text{ eV} - 2.3\text{ eV} = 4.23\text{ eV},$ which rounds to 4.2 eV. The stopping potential is 4.2 volts.

(b) $\frac{1}{2}mv_{\text{max}}^2 = 4.2\text{ eV}.$

(c) $v_{\text{max}} = \sqrt{\dfrac{2(4.23\text{ eV})(1.60\times10^{-19}\text{ J/eV})}{9.11\times10^{-31}\text{kg}}} = 1.2\times10^{6}\text{ m/s}.$

EVALUATE: If the wavelength of the light is decreased, the maximum kinetic energy of the photoelectrons increases.

38.9. **(b) IDENTIFY:** Solve part (b) first. First use $eV_0 = hf - \phi$ to find the work function ϕ

SET UP: $eV_0 = hf - \phi$, so $\phi = hf - eV_0 = \dfrac{hc}{\lambda} - eV_0.$

EXECUTE: $\phi = \dfrac{(6.626\times10^{-34}\text{ J}\cdot\text{s})(2.998\times10^{8}\text{ m/s})}{254\times10^{-9}\text{ m}} - (1.602\times10^{-19}\text{ C})(0.181\text{ V}).$

$\phi = 7.821\times10^{-19}\text{ J} - 2.900\times10^{-20}\text{ J} = 7.531\times10^{-19}\text{ J}(1\text{ eV}/1.602\times10^{-19}\text{ J}) = 4.70\text{ eV}.$

(a) IDENTIFY and **SET UP:** The threshold frequency f_{th} is the smallest frequency that still produces photoelectrons. It corresponds to $K_{\text{max}} = 0$ in the equation $\frac{1}{2}mv_{\text{max}}^2 = hf - \phi$, so $hf_{\text{th}} = \phi.$

EXECUTE: $f = \dfrac{c}{\lambda}$ says $\dfrac{hc}{\lambda_{\text{th}}} = \phi.$

$$\lambda_{\text{th}} = \frac{hc}{\phi} = \frac{(6.626\times10^{-34}\text{ J}\cdot\text{s})(2.998\times10^{8}\text{ m/s})}{7.531\times10^{-19}\text{ J}} = 2.64\times10^{-7}\text{ m} = 264\text{ nm}.$$

EVALUATE: As calculated in part (b), $\phi = 4.70\text{ eV}.$ This is the value given in Table 38.1 for copper.

38.10. **IDENTIFY:** The acceleration gives energy to the electrons which is then given to the x ray photons.

SET UP: $E = hc/\lambda$, so $\dfrac{hc}{\lambda} = eV$, where λ is the wavelength of the x ray and V is the accelerating voltage.

EXECUTE: $\lambda = \dfrac{hc}{eV} = \dfrac{(6.63\times10^{-34}\text{ J}\cdot\text{s})(3.00\times10^{8}\text{ m/s})}{(1.60\times10^{-19}\text{ C})(15.0\times10^{3}\text{ V})} = 8.29\times10^{-11}\text{ m} = 0.0829\text{ nm}.$

EVALUATE: This wavelength certainly is in the x ray region of the electromagnetic spectrum.

38.11. **IDENTIFY:** This problem is about the characteristics of photons.

SET UP: $E = hf$, $\lambda = h/p$, $f\lambda = c$. We want the frequency, wavelength, and momentum of the photon.

EXECUTE: $E_{ph} = 0.700K_{el} = 0.700eV = hf$. So $f = (0.700eV)/h$. Using $V = 50.0$ kV and h in terms of eV, we get $f = 8.46 \times 10^{18}$ Hz. Using this result gives $\lambda = c/f = 0.0355$ nm. Using this wavelength gives $p = h/\lambda = 1.87 \times 10^{-23}\ \text{kg}\cdot\text{m/s}$.

EVALUATE: The frequency of this photon is much greater than that of visible light.

38.12. **IDENTIFY** and **SET UP:** $\dfrac{hc}{\lambda} = eV$, where λ is the wavelength of the x ray and V is the accelerating voltage.

EXECUTE: **(a)** $V = \dfrac{hc}{e\lambda} = \dfrac{(6.63\times10^{-34}\ \text{J}\cdot\text{s})(3.00\times10^{8}\ \text{m/s})}{(1.60\times10^{-19}\ \text{C})(0.150\times10^{-9}\ \text{m})} = 8.29\ \text{kV}.$

(b) $\lambda = \dfrac{hc}{eV} = \dfrac{(6.63\times10^{-34}\ \text{J}\cdot\text{s})(3.00\times10^{8}\ \text{m/s})}{(1.60\times10^{-19}\ \text{C})(30.0\times10^{3}\ \text{V})} = 4.14\times10^{-11}\ \text{m} = 0.0414\ \text{nm}.$

EVALUATE: Shorter wavelengths require larger potential differences.

38.13. **IDENTIFY:** Energy is conserved when the x ray collides with the stationary electron.

SET UP: $E = hc/\lambda$, and energy conservation gives $\dfrac{hc}{\lambda} = \dfrac{hc}{\lambda'} + K_e$.

EXECUTE: Solving for K_e gives $K_e = hc\left(\dfrac{1}{\lambda} - \dfrac{1}{\lambda'}\right) = (6.63\times10^{-34}\ \text{J}\cdot\text{s})(3.00\times10^{8}\ \text{m/s})$
$\left(\dfrac{1}{0.100\times10^{-9}\ \text{m}} - \dfrac{1}{0.110\times10^{-9}\ \text{m}}\right)$. $K_e = 1.81\times10^{-16}\ \text{J} = 1.13\ \text{keV}.$

EVALUATE: The electron does not get all the energy of the incident photon.

38.14. **IDENTIFY** and **SET UP:** The wavelength of the x rays produced by the tube is given by $\dfrac{hc}{\lambda} = eV$.
$\lambda' = \lambda + \dfrac{h}{mc}(1-\cos\phi)$. $\dfrac{h}{mc} = 2.426\times10^{-12}$ m. The energy of the scattered x ray is $\dfrac{hc}{\lambda'}$.

EXECUTE: **(a)** $\lambda = \dfrac{hc}{eV} = \dfrac{(6.63\times10^{-34}\ \text{J}\cdot\text{s})(3.00\times10^{8}\ \text{m/s})}{(1.60\times10^{-19}\ \text{C})(24.0\times10^{3}\ \text{V})} = 5.167\times10^{-11}\ \text{m},$ which rounds to 0.0517 nm = 51.7 pm.

(b) $\lambda' = \lambda + \dfrac{h}{mc}(1-\cos\phi) = 5.167\times10^{-11}\ \text{m} + (2.426\times10^{-12}\ \text{m})(1-\cos 45.0°) = 5.238\times10^{-11}\ \text{m},$ which rounds to 0.0524 nm = 52.4 pm.

(c) $E = \dfrac{hc}{\lambda'} = \dfrac{(4.136\times10^{-15}\ \text{eV}\cdot\text{s})(3.00\times10^{8}\ \text{m/s})}{5.238\times10^{-11}\ \text{m}} = 2.37\times10^{4}\ \text{eV} = 23.7\ \text{keV}.$

EVALUATE: The incident x ray has energy 24.0 keV. In the scattering event, the photon loses energy and its wavelength increases.

38.15. **IDENTIFY:** Apply $\lambda' - \lambda = \dfrac{h}{mc}(1-\cos\phi) = \lambda_C(1-\cos\phi)$.

SET UP: Solve for λ': $\lambda' = \lambda + \lambda_C(1-\cos\phi)$.
The largest λ' corresponds to $\phi = 180°$, so $\cos\phi = -1$.

EXECUTE: $\lambda' = \lambda + 2\lambda_C = 0.0665\times10^{-9}\ \text{m} + 2(2.426\times10^{-12}\ \text{m}) = 7.135\times10^{-11}\ \text{m} = 0.0714\ \text{nm}.$ This wavelength occurs at a scattering angle of $\phi = 180°$.

EVALUATE: The incident photon transfers some of its energy and momentum to the electron from which it scatters. Since the photon loses energy its wavelength increases, $\lambda' > \lambda$.

38.16. **IDENTIFY:** Compton scattering occurs. We know speed, and hence the kinetic energy, of the scattered electron. Energy is conserved.

SET UP: $\dfrac{hc}{\lambda} = \dfrac{hc}{\lambda'} + E_e$ where $E_e = \frac{1}{2}mv^2$.

EXECUTE: $E_e = \frac{1}{2}mv^2 = \frac{1}{2}(9.108\times10^{-31}\text{ kg})(8.90\times10^6\text{ m/s})^2 = 3.607\times10^{-17}\text{ J}$.

$\dfrac{hc}{\lambda} = \dfrac{(6.626\times10^{-34}\text{ J}\cdot\text{s})(2.998\times10^8\text{ m/s})}{0.1385\times10^{-9}\text{ m}} = 1.434\times10^{-15}\text{ J}$. Therefore, $\dfrac{hc}{\lambda'} = \dfrac{hc}{\lambda} - E_e = 1.398\times10^{-15}\text{ J}$,

which gives $\lambda' = \dfrac{(6.626\times10^{-34}\text{ J}\cdot\text{s})(2.998\times10^8\text{ m/s})}{1.398\times10^{-15}\text{ J}} = 0.1421\text{ nm}$.

$\lambda' - \lambda = \left(\dfrac{h}{mc}\right)(1-\cos\phi) = 3.573\times10^{-12}\text{ m}$, so $1-\cos\phi = 1.473$, which gives $\phi = 118°$.

EVALUATE: The photon partly backscatters, but not through 180°.

38.17. **IDENTIFY** and **SET UP:** The shift in wavelength of the photon is $\lambda' - \lambda = \dfrac{h}{mc}(1-\cos\phi)$ where λ' is the wavelength after the scattering and $\dfrac{h}{mc} = \lambda_C = 2.426\times10^{-12}\text{ m}$. The energy of a photon of wavelength λ is $E = \dfrac{hc}{\lambda} = \dfrac{1.24\times10^{-6}\text{ eV}\cdot\text{m}}{\lambda}$. Conservation of energy applies to the collision, so the energy lost by the photon equals the energy gained by the electron.

EXECUTE:

(a) $\lambda' - \lambda = \lambda_C(1-\cos\phi) = (2.426\times10^{-12}\text{ m})(1-\cos 35.0°) = 4.39\times10^{-13}\text{ m} = 4.39\times10^{-4}\text{ nm}$.

(b) $\lambda' = \lambda + 4.39\times10^{-4}\text{ nm} = 0.04250\text{ nm} + 4.39\times10^{-4}\text{ nm} = 0.04294\text{ nm}$.

(c) $\lambda' - \lambda = \left(\dfrac{h}{mc}\right)(1-\cos\phi) = 0.1050\times10^{-9}\text{ m} + (2.426\times10^{-12}\text{ m})(1-\cos 60.0°) = 0.1062\times10^{-9}\text{ m}$ and

$E_{\lambda'} = \dfrac{hc}{\lambda'} = 2.888\times10^4\text{ eV}$, so the photon loses 300 eV of energy.

(d) Energy conservation says the electron gains 300 eV of energy.

EVALUATE: The photon transfers energy to the electron. Since the photon loses energy, its wavelength increases.

38.18. **IDENTIFY:** The change in wavelength of the scattered photon is given by the equation

$$\frac{\Delta\lambda}{\lambda} = \frac{h}{mc\lambda}(1-\cos\phi) \Rightarrow \lambda = \frac{h}{mc\left(\dfrac{\Delta\lambda}{\lambda}\right)}(1-\cos\phi).$$

SET UP: For backward scattering, $\phi = 180°$. Since the photon scatters from a proton, $m = 1.67\times10^{-27}\text{ kg}$.

EXECUTE: $\lambda = \dfrac{(6.63\times10^{-34}\text{ J}\cdot\text{s})}{(1.67\times10^{-27}\text{ kg})(3.00\times10^8\text{ m/s})(0.100)}(1+1) = 2.65\times10^{-14}\text{ m}$.

EVALUATE: The maximum change in wavelength, $2h/mc$, is much smaller for scattering from a proton than from an electron.

38.19. **IDENTIFY:** We are dealing with Compton scattering.

SET UP: $\lambda = h/p$, $E = hc/\lambda$, $\lambda' - \lambda = \dfrac{h}{mc}(1-\cos\phi)$.

EXECUTE: **(a)** The initial photon lost energy during Compton scattering. Before this it had just enough energy to create electron-positron pairs, so after the collision it has less energy. Therefore it cannot create these pairs, so the answer is no.

(b) We want the momentum of the scattered photon. First use find λ' using

$$\lambda' - \lambda = \frac{h}{mc}(1 - \cos\phi)$$

and then use $\lambda = h/p$ to find the momentum. Before scattering $E = 2mc^2 = hc/\lambda$, so $\lambda = h/2mc$.

$$\lambda' = \frac{h}{mc}(1 - \cos\phi) + \frac{h}{2mc} = \frac{h}{mc}\left(\frac{3}{2} - \cos\phi\right).$$

Using this result gives with $\phi = 20.0°$ gives

$$p = \frac{h}{\lambda'} = \frac{h}{\frac{h}{mc}\left(\frac{3}{2} - \cos\phi\right)} = \frac{mc}{\frac{3}{2} - \cos\phi} = 4.88 \times 10^{-22}\ \text{kg} \cdot \text{m/s}.$$

EVALUATE: The momentum of the scattered photon depends on the scattering angle ϕ. The smallest that the momentum can be is when $\cos\phi = -1$ ($\phi = 180°$, which is backscatter), for which $p_{\text{min}} = 2mc/5$.

38.20. **(a) IDENTIFY** and **SET UP:** Use the relativistic equation $K = (\gamma - 1)mc^2$ to calculate the kinetic energy K.

EXECUTE: $K = mc^2\left(\frac{1}{\sqrt{1 - v^2/c^2}} - 1\right) = 0.1547\ mc^2$. $m = 9.109 \times 10^{-31}$ kg, so $K = 1.27 \times 10^{-14}$ J.

(b) IDENTIFY and **SET UP:** The total energy of the particles equals the sum of the energies of the two photons. Linear momentum must also be conserved.

EXECUTE: The total energy of each electron or positron is $E = K + mc^2 = 1.1547mc^2 = 9.46 \times 10^{-13}$ J. The total energy of the electron and positron is converted into the total energy of the two photons. The initial momentum of the system in the lab frame is zero (since the equal-mass particles have equal speeds in opposite directions), so the final momentum must also be zero. The photons must have equal wavelengths and must be traveling in opposite directions. Equal λ means equal energy, so each photon has energy 9.46×10^{-14} J.

(c) IDENTIFY and **SET UP:** Use $E = hc/\lambda$ to relate the photon energy to the photon wavelength.

EXECUTE: $E = hc/\lambda$, so $\lambda = hc/E = hc/(9.46 \times 10^{-14}\ \text{J}) = 2.10$ pm.

EVALUATE: When the particles also have kinetic energy, the energy of each photon is greater, so its wavelength is less.

38.21. **IDENTIFY:** The wavelength of the pulse tells us the momentum of the photon. The uncertainty in the momentum is determined by the uncertainty principle.

SET UP: $p = \frac{h}{\lambda}$ and $\Delta x \Delta p_x = \frac{\hbar}{2}$.

EXECUTE: $p = \frac{h}{\lambda} = \frac{6.626 \times 10^{-34}\ \text{J} \cdot \text{s}}{556 \times 10^{-9}\ \text{m}} = 1.19 \times 10^{-27}\ \text{kg} \cdot \text{m/s}$. The spatial length of the pulse is $\Delta x = c\Delta t = (2.998 \times 10^8\ \text{m/s})(9.00 \times 10^{-15}\ \text{s}) = 2.698 \times 10^{-6}$ m. The uncertainty principle gives $\Delta x \Delta p_x = \frac{\hbar}{2}$. Solving for the uncertainty in the momentum, we have $\Delta p_x = \frac{\hbar}{2\Delta x} = \frac{1.055 \times 10^{-34}\ \text{J} \cdot \text{s}}{2(2.698 \times 10^{-6}\ \text{m})}$ $= 1.96 \times 10^{-29}\ \text{kg} \cdot \text{m/s}$.

EVALUATE: This is 1.6% of the average momentum.

38.22. **IDENTIFY:** We know the beam went through the slit, so the uncertainty in its vertical position is the width of the slit.

SET UP: $\Delta y \Delta p_y = \dfrac{\hbar}{2}$ and $p_x = \dfrac{h}{\lambda}$. Call the x-axis horizontal and the y-axis vertical.

EXECUTE: **(a)** Let $\Delta y = a = 6.20\times10^{-5}$ m. Solving $\Delta y \Delta p_y = \dfrac{\hbar}{2}$ for the uncertainty in momentum gives

$$\Delta p_y = \frac{\hbar}{2\Delta y} = \frac{1.055\times10^{-34}\ \text{J}\cdot\text{s}}{2(6.20\times10^{-5}\ \text{m})} = 8.51\times10^{-31}\ \text{kg}\cdot\text{m/s}.$$

(b) $p_x = \dfrac{h}{\lambda} = \dfrac{6.626\times10^{-34}\ \text{J}\cdot\text{s}}{585\times10^{-9}\ \text{m}} = 1.13\times10^{-27}\ \text{kg}\cdot\text{m/s}.$ $\theta = \dfrac{\Delta p_y}{p_x} = \dfrac{8.51\times10^{-31}}{1.13\times10^{-27}} = 7.53\times10^{-4}$ rad.

The width is $(2.00\ \text{m})(7.53\times10^{-4}) = 1.51\times10^{-3}\ \text{m} = 1.51$ mm.

EVALUATE: We must be especially careful not to confuse the x- and y-components of the momentum.

38.23. **IDENTIFY:** The uncertainty principle relates the uncertainty in the duration time of the pulse and the uncertainty in its energy, which we know.

SET UP: $E = hc/\lambda$ and $\Delta E \Delta t = \hbar/2$.

EXECUTE: $E = \dfrac{hc}{\lambda} = \dfrac{(6.626\times10^{-34}\ \text{J}\cdot\text{s})(2.998\times10^{8}\ \text{m/s})}{625\times10^{-9}\ \text{m}} = 3.178\times10^{-19}$ J. The uncertainty in the energy is 1.0% of this amount, so $\Delta E = 3.178\times10^{-21}$ J. We now use the uncertainty principle. Solving $\Delta E \Delta t = \dfrac{\hbar}{2}$ for the time interval gives $\Delta t = \dfrac{\hbar}{2\Delta E} = \dfrac{1.055\times10^{-34}\ \text{J}\cdot\text{s}}{2(3.178\times10^{-21}\ \text{J})} = 1.66\times10^{-14}\ \text{s} = 16.6$ fs.

EVALUATE: The uncertainty in the energy limits the duration of the pulse. The more precisely we know the energy, the longer the duration must be.

38.24. **IDENTIFY:** The number N of visible photons emitted per second is the visible power divided by the energy hf of one photon.

SET UP: At a distance r from the source, the photons are evenly spread over a sphere of area $A = 4\pi r^2$.

EXECUTE: **(a)** $N = \dfrac{P}{hf} = \dfrac{(120\ \text{W})(0.10)}{h(5.00\times10^{14}\ \text{Hz})} = 3.62\times10^{19}$ photons/s.

(b) $\dfrac{N}{4\pi r^2} = 1.00\times10^{11}\ \text{photons/s}\cdot\text{cm}^2$ gives

$$r = \left(\frac{3.62\times10^{19}\,\text{photons/s}}{4\pi(1.00\times10^{11}\ \text{photons/s}\cdot\text{cm}^2)}\right)^{1/2} = 5370\ \text{cm} = 53.7\ \text{m}.$$

EVALUATE: The number of photons emitted per second by an ordinary household source is very large.

38.25. **IDENTIFY** and **SET UP:** The energy added to mass m of the blood to heat it to $T_\text{f} = 100°\text{C}$ and to vaporize it is $Q = mc(T_\text{f} - T_\text{i}) + mL_\text{v}$, with $c = 4190$ J/kg $\cdot$ K and $L_\text{v} = 2.256\times10^{6}$ J/kg. The energy of one photon is $E = \dfrac{hc}{\lambda} = \dfrac{1.99\times10^{-25}\ \text{J}\cdot\text{m}}{\lambda}$.

EXECUTE: **(a)** $Q = (2.0\times10^{-9}\ \text{kg})(4190\ \text{J/kg}\cdot\text{K})(100°\text{C} - 33°\text{C}) + (2.0\times10^{-9}\ \text{kg})(2.256\times10^{6}\ \text{J/kg}) =$ 5.07×10^{-3} J. The pulse must deliver 5.07 mJ of energy.

(b) $P = \dfrac{\text{energy}}{t} = \dfrac{5.07\times10^{-3}\ \text{J}}{450\times10^{-6}\ \text{s}} = 11.3$ W.

(c) One photon has energy $E = \dfrac{hc}{\lambda} = \dfrac{1.99\times10^{-25}\ \text{J}\cdot\text{m}}{585\times10^{-9}\ \text{m}} = 3.40\times10^{-19}\ \text{J}$. The number N of photons per pulse is the energy per pulse divided by the energy of one photon:

$$N = \frac{5.07\times10^{-3}\ \text{J}}{3.40\times10^{-19}\ \text{J/photon}} = 1.49\times10^{16}\ \text{photons.}$$

EVALUATE: The power output of the laser is small but it is focused on a small area, so the laser intensity is large.

38.26. **IDENTIFY:** The photoelectric effect occurs, so the energy of the photon is used to eject an electron, with any excess energy going into kinetic energy of the electron.
SET UP: Conservation of energy gives $hf = hc/\lambda = K_{\text{max}} + \phi.$

EXECUTE: **(a)** Using $hc/\lambda = K_{\text{max}} + \phi,$ we solve for the work function:

$$\phi = hc/\lambda - K_{\text{max}} = (4.136\times10^{-15}\ \text{eV}\cdot\text{s})(3.00\times10^{8}\ \text{m/s})/(124\ \text{nm}) - 4.16\ \text{eV} = 5.85\ \text{eV}.$$

(b) The number N of photoelectrons per second is equal to the number of photons that strike the metal per second. $N\times(\text{energy of a photon}) = 2.50\ \text{W}$. $N(hc/\lambda) = 2.50\ \text{W}$.

$$N = (2.50\ \text{W})(124\ \text{nm})/[(6.626\times10^{-34}\ \text{J}\cdot\text{s})(3.00\times10^{8}\ \text{m/s})] = 1.56\times10^{18}\ \text{electrons/s.}$$

(c) N is proportional to the power, so if the power is cut in half, so is N, which gives

$$N = (1.56\times10^{18}\ \text{el/s})/2 = 7.80\times10^{17}\ \text{el/s.}$$

(d) If we cut the wavelength by half, the energy of each photon is doubled since $E = hc/\lambda.$ To maintain the same power, the number of photons must be half of what they were in part (b), so N is cut in half to 7.80×10^{17} el/s. We could also see this from part (b), where N is proportional to $\lambda.$ So if the wavelength is cut in half, so is N.
EVALUATE: In part (c), reducing the power does not reduce the maximum kinetic energy of the photons; it only reduces the number of ejected electrons. In part (d), reducing the wavelength *does* change the maximum kinetic energy of the photoelectrons because we have increased the energy of each photon.

38.27. **IDENTIFY:** We are dealing with the characteristics of a photon.
SET UP and **EXECUTE:** Using $E = hc/\lambda,$ we want to estimate the number of photons in a typical room.

(a) Estimate: On a bright day the light intensity in a room is about 1/3 of what it is outside, so

$$I = (1000\ \text{W/m}^2)/3 = 330\ \text{W/m}^2.$$

(b) Estimate: Floor area is $A \approx 15$ ft by 30 ft ≈ 5 m by 10 m $\approx 50\ \text{m}^2$. Height is $H \approx 9$ ft ≈ 3 m.
(c) $t = H/c = (3\ \text{m})/c = 10^{-8}\ \text{s} = 10$ ns.
(d) $P = IA = (330\ \text{W/m}^2)(50\ \text{m}^2) = 16{,}500$ W.
(e) $E_{\text{room}} = Pt = (16{,}500\ \text{W})(10^{-8}\ \text{s}) = 165\ \mu\text{J}$.
(f) $E = hc/\lambda = hc/(500\ \text{nm}) = 3.98\times10^{-19}$ J.
(g) Using the answers from parts (e) and (f) gives $N = E_{\text{room}}/E = 4\times10^{14}$.
EVALUATE: These numbers give only rough approximations, not precise calculations.

38.28. **IDENTIFY:** Compton scattering occurs. For backscattering, the scattering angle of the photon is 180°. Momentum is conserved during the collision.
SET UP: Let $+x$ be in the direction of propagation of the incident photon. The momentum of a photon is $p = h/\lambda.$ The change in wavelength of the light during Compton scattering is given by

$\lambda' - \lambda = \left(\dfrac{h}{mc}\right)(1-\cos\phi),$ where $\phi = 180°$ in this case.

EXECUTE: $\lambda' = \lambda + 2\dfrac{h}{mc} = 0.0980\times10^{-9}\text{ m} + 4.852\times10^{-12}\text{ m} = 0.1029\times10^{-9}\text{ m}$. Momentum conservation gives $\dfrac{h}{\lambda} = -\dfrac{h}{\lambda'} + p_e$. Solving for p_e gives $p_e = \dfrac{h}{\lambda} + \dfrac{h}{\lambda'} = h\left(\dfrac{\lambda+\lambda'}{\lambda\lambda'}\right) = (6.626\times10^{-34}\text{ J}\cdot\text{s})$
$\dfrac{9.80\times10^{-11}\text{ m} + 10.29\times10^{-11}\text{ m}}{(9.80\times10^{-11}\text{ m})(10.29\times10^{-11}\text{ m})} = 1.32\times10^{-23}\text{ kg}\cdot\text{m/s}$.

EVALUATE: The electron gains the most amount of momentum when backscattering occurs.

38.29. IDENTIFY: Compton scattering occurs, and we know the angle of scattering and the initial wavelength (and hence momentum) of the incident photon.

SET UP: $\lambda' - \lambda = \left(\dfrac{h}{mc}\right)(1-\cos\phi)$ and $p = h/\lambda$. Let $+x$ be the direction of propagation of the incident photon and let the scattered photon be moving at $30.0°$ clockwise from the $+y$-axis.

EXECUTE:

$$\lambda' - \lambda = \left(\frac{h}{mc}\right)(1-\cos\phi) = 0.1050\times10^{-9}\text{ m} + (2.426\times10^{-12}\text{ m})(1-\cos 60.0°) = 0.1062\times10^{-9}\text{ m}.$$

$P_{ix} = P_{fx}$. $\dfrac{h}{\lambda} = \dfrac{h}{\lambda'}\cos 60.0° + p_{ex}$.

$$p_{ex} = \frac{h}{\lambda} - \frac{h}{2\lambda'} = h\frac{2\lambda' - \lambda}{(2\lambda')(\lambda)} = (6.626\times10^{-34}\text{ J}\cdot\text{s})\frac{2.1243\times10^{-10}\text{ m} - 1.050\times10^{-10}\text{ m}}{(2.1243\times10^{-10}\text{ m})(1.050\times10^{-10}\text{ m})}.$$

$p_{ex} = 3.191\times10^{-24}\text{ kg}\cdot\text{m/s}$. $P_{iy} = P_{fy}$. $0 = \dfrac{h}{\lambda'}\sin 60.0° + p_{ey}$.

$$p_{ey} = -\frac{(6.626\times10^{-34}\text{ J}\cdot\text{s})\sin 60.0°}{0.1062\times10^{-9}\text{ m}} = -5.403\times10^{-24}\text{ kg}\cdot\text{m/s}. \quad p_e = \sqrt{p_{ex}^2 + p_{ey}^2} = 6.28\times10^{-24}\text{ kg}\cdot\text{m/s}.$$

$\tan\theta = \dfrac{p_{ey}}{p_{ex}} = \dfrac{-5.403}{3.191}$ and $\theta = -59.4°$.

EVALUATE: The incident photon does not give all of its momentum to the electron, since the scattered photon also has momentum.

38.30. IDENTIFY: This problem deals with photons and the nutritional energy in food.
SET UP and **EXECUTE:** **(a)** Estimate: One medium tomato (123 g) has 22 kcal.

(22 kcal)(4186 J/kcal) = 93,000 J.

(b) Estimate: 50 leaves of area 20 cm^2 each, so $A \approx 1000\text{ cm}^2 = 0.10\text{ m}^2$.
(c) $P = IA = (800\text{ W/m}^2)(0.10\text{ m}^2) = 80\text{ W}$.
(d) $E = hc/\lambda = hc/(600\text{ nm}) = 3.31\times10^{-19}$ J per photon. The total energy each second for photosynthesis is 5% of 80 J = 4.0 J. The number N of photons needed to deliver this energy is given by $N(3.31\times10^{-19}\text{ J}) = 4.0$ J, so $N = 1.2\times10^{19}$ photons.
(e) The number N' of photons for a single tomato is $N' = (1/10)(N/2) = 6.0\times10^{17}$ photons.
(f) Each tomato needs 93,000 J from part (a). If N is the number of photons needed, then $N(3.31\times10^{-19}\text{ J}) = 93{,}000$ J, which gives $N = 2.82\times10^{23}$ photons.
(g) From part (e): 6.0×10^{27} photons/s supply energy to the tomato.
From part (f): The tomato needs 2.82×10^{23} photons.
Calling t the time to get these photons gives $(6.0\times10^{17}\text{ photons/s})t = 2.82\times10^{23}$ photons, which gives $t = 4.7\times10^5$ s = 131 h. At 12 h/day, we get t = 11 days.

EVALUATE: Increasing the leaf area exposed to sunlight would help capture more energy and lead to faster ripening.

38.31. **IDENTIFY** and **SET UP:** Find the average change in wavelength for one scattering and use that in $\Delta\lambda$ in $\lambda' - \lambda = \left(\dfrac{h}{mc}\right)(1-\cos\phi)$ to calculate the average scattering angle ϕ.

EXECUTE: **(a)** The wavelength of a 1 MeV photon is

$\lambda = \dfrac{hc}{E} = \dfrac{(4.136\times10^{-15}\ \text{eV}\cdot\text{s})(2.998\times10^{8}\ \text{m/s})}{1\times10^{6}\ \text{eV}} = 1\times10^{-12}\ \text{m}.$

The total change in wavelength therefore is $500\times10^{-9}\ \text{m} - 1\times10^{-12}\ \text{m} = 500\times10^{-9}\ \text{m}.$

If this shift is produced in 10^{26} Compton scattering events, the wavelength shift in each scattering event is $\Delta\lambda = \dfrac{500\times10^{-9}\ \text{m}}{1\times10^{26}} = 5\times10^{-33}\ \text{m}.$

(b) Use this $\Delta\lambda$ in $\Delta\lambda = \dfrac{h}{mc}(1-\cos\phi)$ and solve for ϕ. We anticipate that ϕ will be very small, since $\Delta\lambda$ is much less than h/mc, so we can use $\cos\phi \approx 1-\phi^2/2.$

$$\Delta\lambda = \frac{h}{mc}\left[1-(1-\phi^2/2)\right] = \frac{h}{2mc}\phi^2.$$

$$\phi = \sqrt{\frac{2\Delta\lambda}{(h/mc)}} = \sqrt{\frac{2(5\times10^{-33}\ \text{m})}{2.426\times10^{-12}\ \text{m}}} = 6.4\times10^{-11}\ \text{rad} = (4\times10^{-9})°.$$

ϕ in radians is much less than 1, so the approximation we used is valid.

(c) **IDENTIFY** and **SET UP:** We know the total transit time and the total number of scatterings, so we can calculate the average time between scatterings.

EXECUTE: The total time to travel from the core to the surface is $(10^6\ \text{y})(3.156\times10^7\ \text{s/y}) = 3.2\times10^{13}\ \text{s}.$

There are 10^{26} scatterings during this time, so the average time between scatterings is

$t = \dfrac{3.2\times10^{13}\ \text{s}}{10^{26}} = 3.2\times10^{-13}\ \text{s}.$

The distance light travels in this time is $d = ct = (3.0\times10^8\ \text{m/s})(3.2\times10^{-13}\ \text{s}) = 0.1\ \text{mm}.$

EVALUATE: The photons are on the average scattered through a very small angle in each scattering event. The average distance a photon travels between scatterings is very small.

38.32. **IDENTIFY:** In this problem, a positron with speed v and kinetic energy K collides with a stationary electron. They annihilate and produce to two photons each of wavelength λ .

SET UP: $E = hc/\lambda,\ \ K = mc^2(\gamma-1),\ \ p = m\gamma v,\ \ v'_x = \dfrac{v_x - u}{1-uv_x/c^2}.$

EXECUTE: **(a)** Energy conservation: $K + mc^2 + mc^2 = 2hc/\lambda.$ Using $K = mc^2(\gamma-1)$ gives

$$(\gamma-1)mc^2 + 2mc^2 = 2hc/\lambda.$$

Rearranging gives

$$(\gamma+1)mc^2 = 2hc/\lambda.$$

(b) Momentum conservation: Using $p = m\gamma v$ for the positron gives

$$m\gamma v = 2\frac{h}{\lambda}\cos\phi.$$

(c) We want the energy of the photon and the angle ϕ.

From part (a): $(\gamma+1)mc^2 = 2hc/\lambda = 2E_{\text{photon}}.$

This gives $E_{\text{photon}} = \dfrac{mc^2(\gamma+1)}{2}.$

From part (b): $m\gamma v = 2\dfrac{h}{\lambda}\cos\phi$. This gives $\cos\phi = \dfrac{m\gamma v\lambda}{2h}$.

Combine the results from (a) and (b) by eliminating λ and solve for $\cos\phi$.

$$\cos\phi = \frac{\gamma v}{c(1+\gamma)}.$$

Using $v = c\sqrt{1-1/\gamma^2}$ and doing some algebra gives

$$\phi = \arccos\sqrt{\frac{\gamma-1}{\gamma+1}}.$$

(d) We want the energy of the photon and the angle z if K = 5.11 MeV. Using $K = mc^2(\gamma-1)$ with mc^2 = 0.511 MeV gives γ = 11. From part (c)

$$\phi = \arccos\sqrt{\frac{\gamma-1}{\gamma+1}} = 3.07\text{ MeV}.$$

Also from part (c) we get

$$\phi = \arccos\sqrt{\frac{\gamma-1}{\gamma+1}} = \arccos\sqrt{\frac{10}{12}} = 24.1°.$$

(e) We want *v* if the photons are perpendicular to each other. In this case, ϕ = 45.0°. Solving

$\phi = \arccos\sqrt{\dfrac{\gamma-1}{\gamma+1}}$ gives $\gamma = 2$. Using $v = c\sqrt{1-1/\gamma^2}$ gives v = 0.866c.

(f) We want to transform to the center-of-momentum frame where the total momentum is zero. Call *u* the speed of this reference frame. In this frame, the electron and positron have equal but opposite velocities. Use the relativistic velocity addition equation $v'_x = \dfrac{v_x - u}{1 - uv_x/c^2}$, with *R* the lab frame and R' the center-of-momentum frame. We want to find *u*.

For the positron: $v'_{\text{px}} = \dfrac{v-u}{1-uv/c^2}$

For the electron: $v'_{ex} = \dfrac{0-u}{1-0} = -u$

In the center-of-momentum frame, $v'_{\text{px}} = -v'_{\text{ex}}$, so $v'_{\text{px}} = \dfrac{v-u}{1-uv/c^2} = -(-u) = u$. This leads to the equation $u^2(v/c^2) - 2u + v = 0$. Solve this equation for *u*, use the positive root, and use $v = c\sqrt{1-1/\gamma^2}$.
The result is

$$u = v\frac{\gamma}{\gamma+1} = c\sqrt{\frac{\gamma-1}{\gamma+1}}.$$

EVALUATE: Check: If $v \ll c$, c= 1, so $u = v\dfrac{\gamma}{\gamma+1} = v\dfrac{1}{1+1} = \dfrac{v}{2}$. This result is reasonable because in the center-of-momentum frame without using special relativity the electron and positron are coming toward each other each with speed $v/2$.

38.33. IDENTIFY and SET UP: Conservation of energy applied to the collision gives $E_\lambda = E_{\lambda'} + E_{\text{e}}$, where E_{e} is the kinetic energy of the electron after the collision and E_λ and $E_{\lambda'}$ are the energies of the photon before and after the collision. The energy of a photon is related to its wavelength according to $E = hf = hc/\lambda$.

EXECUTE: **(a)** $E_e = hc\left(\frac{1}{\lambda} - \frac{1}{\lambda'}\right) = hc\left(\frac{\lambda' - \lambda}{\lambda\lambda'}\right).$

$E_e = (6.626\times10^{-34}\ \text{J}\cdot\text{s})(2.998\times10^{8}\ \text{m/s})\left(\frac{0.0032\times10^{-9}\ \text{m}}{(0.1100\times10^{-9}\ \text{m})(0.1132\times10^{-9}\ \text{m})}\right).$

$E_e = 5.105\times10^{-17}\ \text{J} = 319\ \text{eV}.$

$E_e = \frac{1}{2}mv^2$, so $v = \sqrt{\frac{2E_e}{m}} = \sqrt{\frac{2(5.105\times10^{-17}\ \text{J})}{9.109\times10^{-31}\ \text{kg}}} = 1.06\times10^{7}\ \text{m/s}.$

(b) The wavelength λ of a photon with energy E_e is given by $E_e = hc/\lambda$, so

$$\lambda = \frac{hc}{E_e} = \frac{(6.626\times10^{-34}\ \text{J}\cdot\text{s})(2.998\times10^{8}\ \text{m/s})}{5.105\times10^{-17}\ \text{J}} = 3.89\ \text{nm}.$$

EVALUATE: Only a small portion of the incident photon's energy is transferred to the struck electron; this is why the wavelength calculated in part (b) is much larger than the wavelength of the incident photon in the Compton scattering.

38.34. **IDENTIFY:** The equation $\lambda' - \lambda = \left(\frac{h}{mc}\right)(1-\cos\phi)$ relates λ and λ' to ϕ. Apply conservation of energy to obtain an expression that relates λ and v to λ'.

SET UP: The kinetic energy of the electron is $K = (\gamma - 1)mc^2$. The energy of a photon is $E = \frac{hc}{\lambda}.$

EXECUTE: **(a)** The final energy of the photon is $E' = \frac{hc}{\lambda'}$, and $E = E' + K$, where K is the kinetic energy of the electron after the collision. Then,

$$\lambda = \frac{hc}{E'+K} = \frac{hc}{(hc/\lambda') + K} = \frac{hc}{(hc/\lambda') + (\gamma-1)mc^2} = \frac{\lambda'}{1 + \frac{\lambda' mc}{h}\left[\frac{1}{(1-v^2/c^2)^{1/2}} - 1\right]}.$$

$(K = mc^2(\gamma - 1)$ since the relativistic expression must be used for three-figure accuracy).

(b) $\phi = \arccos[1 - \Delta\lambda/(h/mc)].$

(c) $\gamma - 1 = \frac{1}{\left(1-\left(\frac{1.80}{3.00}\right)^2\right)^{1/2}} - 1 = 1.25 - 1 = 0.250,\ \frac{h}{mc} = 2.43\times10^{-12}\ \text{m}$

$$\Rightarrow \lambda = \frac{5.10\times10^{-3}\ \text{nm}}{1 + \frac{(5.10\times10^{-12}\ \text{m})(9.11\times10^{-31}\ \text{kg})(3.00\times10^{8}\ \text{m/s})(0.250)}{(6.63\times10^{-34}\ \text{J}\cdot\text{s})}} = 3.34\times10^{-3}\ \text{nm}.$$

$$\phi = \arccos\left(1 - \frac{(5.10\times10^{-12}\ \text{m} - 3.34\times10^{-12}\ \text{m})}{2.43\times10^{-12}\ \text{m}}\right) = 74.0°.$$

EVALUATE: For this final electron speed, $v/c = 0.600$ and $K = \frac{1}{2}mv^2$ is not accurate.

38.35. **IDENTIFY** and **SET UP:** Apply the photoelectric effect. $eV_0 = hf - \phi$. For a photon, $f\lambda = c$.

EXECUTE: **(a)** Using $eV_0 = hf - \phi$ and $f\lambda = c$, we get $eV_0 = hc/\lambda - \phi$. Solving for V_0 gives $V_0 = \frac{hc}{e}\cdot\frac{1}{\lambda} - \frac{\phi}{e}$. Therefore a graph of V_0 versus $1/\lambda$ should be a straight line with slope equal to hc/e and y-intercept equal to $-\phi/e$. Figure 38.35 shows this graph for the data given in the problem. The best-fit equation for this graph is $V_0 = (1230\ \text{V}\cdot\text{nm})\cdot\frac{1}{\lambda} - 4.76\ \text{V}$. The slope is equal to $1230\ \text{V}\cdot\text{nm}$, which is equal to $1.23\times10^{-6}\ \text{V}\cdot\text{m}$, and the y-intercept is –4.76 V.

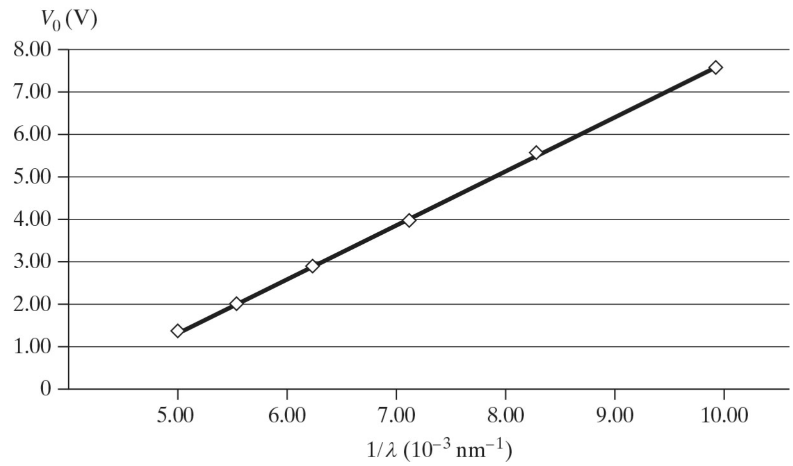

Figure 38.35

(b) Using the slope we have hc/e = slope, so

$h = e(\text{slope})/c = (1.602\times10^{-19}\text{ C})(1.23\times10^{-6}\text{ V}\cdot\text{m})/(2.998\times10^{8}\text{ m/s}) = 6.58\times10^{-34}\text{ J}\cdot\text{s}.$

The y-intercept is equal to $-\phi/e$, so

$$\phi = -e(y\text{-intercept}) = -(1.602\times10^{-19}\text{ C})(-4.76\text{ V}) = 7.63\times10^{-19}\text{ J} = 4.76\text{ eV}.$$

(c) For the longest wavelength light, the energy of a photon is equal to the work function of the metal, so $hc/\lambda = \phi$. Solving for λ gives $\lambda = hc/\phi$. Our calculation of h was just a test of the data, so we use the accepted value for h in the calculation.

$\lambda = hc/\phi = (6.626\times10^{-34}\text{ J}\cdot\text{s})(2.998\times10^{8}\text{ m/s})/(7.63\times10^{-19}\text{ J}) = 2.60\times10^{-7}\text{ m} = 260\text{ nm}.$

(d) The energy of the photon is equal to the sum of the kinetic energy of the photoelectron and the work function, so $hc/\lambda = K + \phi$. This gives $(4.136\times10^{-15}\text{ eV}\cdot\text{s})(2.998\times10^{8}\text{ m/s})/\lambda = 10.0\text{ eV} + 4.76\text{ eV}$ $= 14.76$ eV, which gives $\lambda = 8.40\times10^{-8}$ m = 84.0 nm.

EVALUATE: As we know from Table 38.1, typical metal work functions are several eV, so our results are plausible.

38.36. **IDENTIFY** and **SET UP:** For the photoelectric effect, $eV_0 = hf - \phi$, and the energy of a photon is $E = hf = hc/\lambda$.

EXECUTE: **(a)** The energy of the UV photons is

$$E = hc/\lambda = (4.136\times10^{-15}\text{ eV}\cdot\text{s})(2.998\times10^{8}\text{ m/s})/(270\times10^{-9}\text{ m}) = 4.59\text{ eV}.$$

The photon energy must be at least as great as the work function to produce photoelectrons. From Table 38.1, we see that this is the case for aluminum, silver, and sodium.

(b) The maximum kinetic energy of a photoelectron is $K = hf - \phi$, so the smallest work function gives the largest kinetic energy of the electron. This is the case for sodium.

$K = E_{\text{photon}} - \phi = 4.59\text{ eV} - 2.7\text{ eV} = 1.89$ eV. This is much less than the rest energy (0.511 MeV) of an electron, so we do not need to use the relativistic formula for kinetic energy. Solving $K = \frac{1}{2}mv^2$ for v gives

$$v = \sqrt{\frac{2K}{m}} = \sqrt{\frac{2(1.89\text{ eV})(1.602\times10^{-19}\text{ J/eV})}{9.11\times10^{-31}\text{ kg}}} = 8.2\times10^{5}\text{ m/s}.$$

(c) The energy of the photon is equal to the work function of the gold, so $hc/\lambda = \phi$. This gives $(4.136\times10^{-15}\text{ eV}\cdot\text{s})(2.998\times10^{8}\text{ m/s})/\lambda = 5.1\text{ eV} \rightarrow \lambda = 2.4\times10^{-7}\text{ m} = 240\text{ nm}.$

(d) In part (c), the energy of the photon is equal to the work function for gold, so

$$K_{\text{max}} = E_{\text{photon}} - \phi_{\text{sodium}} = \phi_{\text{gold}} - \phi_{\text{sodium}} = 5.1\text{ eV} - 2.7\text{ eV} = 2.4\text{ eV}.$$

EVALUATE: Of the three possible metals in Table 38.1, aluminum would be the most practical to use for the smoke detector. Silver is probably too expensive, and sodium is too reactive with water.

38.37. **IDENTIFY** and **SET UP:** We have Compton scattering, so $\lambda' - \lambda = \left(\frac{h}{mc}\right)(1-\cos\phi)$, which can also be expressed as $\lambda' - \lambda = \lambda_C(1-\cos\phi)$, where λ_C is the Compton wavelength.

EXECUTE: **(a)** Figure 38.37 shows the graph of λ' versus $1 - \cos\phi$ for the data included in the problem. The best-fit equation of the line is λ' = 5.21 pm + (2.40 pm)(1 – cos ϕ). The slope is 2.40 pm and the y-intercept is 5.21 pm.

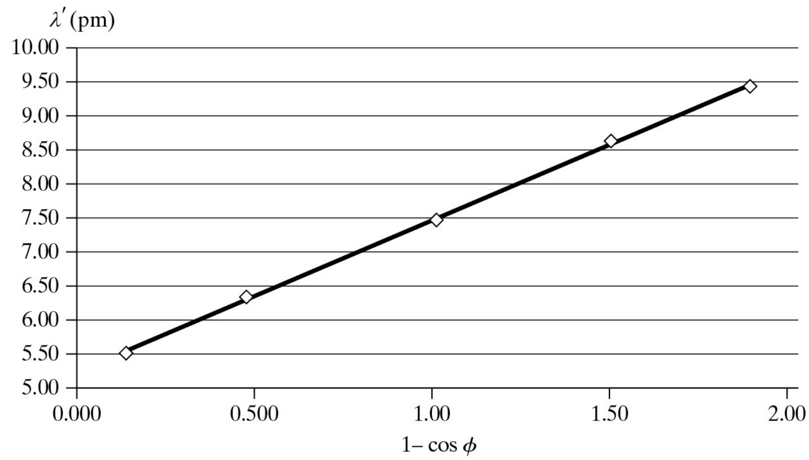

Figure 38.37

(b) Solving $\lambda' - \lambda = \lambda_C(1-\cos\phi)$ for λ' gives $\lambda' = \lambda + \lambda_C(1-\cos\phi)$. The graph of λ' versus $1 - \cos\phi$ should be a straight line with slope equal to λ_C and y-intercept equal to λ. From the slope, we get λ_C = slope = 2.40 pm.

(c) From the y-intercept we get $\lambda = y$-intercept = 5.21 pm.

EVALUATE: For backscatter, the photon wavelength would be 5.21 pm + 2(2.40 pm) = 10.01 pm.

38.38. **IDENTIFY:** In this problem we are dealing with the photoelectric effect and must also use Kirchhoff's rules.

SET UP: $eV_0 = hf - \phi = hc/\lambda - \phi.$

EXECUTE: **(a)** We want V_{AC} if R = 3.20 kΩ.

$$I = \frac{\mathcal{E}}{R_{\text{eq}}} = \frac{15.0\text{ V}}{4.20\text{ k}\Omega} = 3.5714\text{ mA}.$$

$$V_R = RI = (3.20\text{ k}\Omega)(3.5714\text{ mA}) = 11.4\text{ V}.$$

The cathode is at a higher potential than the anode, so $V_{AC} = V_A - V_C = -11.4$ V.

(b) We want V_{AC} if R = 334 Ω. Follow the same procedure as in part (a), which gives

$$V_R = (334\ \Omega)\frac{15.0\text{ V}}{1.334\text{ K}\Omega} = 3.76\text{ V}.$$

Therefore $V_{AC} = -3.76$ V.

(c) We want the work function. From part (b), the stopping potential is 3.76 V. Solving $eV_0 = hc/\lambda - \phi$ for ϕ gives

$$\phi = \frac{hc}{\lambda} - eV_0 = \frac{hc}{140 \text{ nm}} - e(3.76 \text{ V}) = 5.10 \text{ eV}.$$

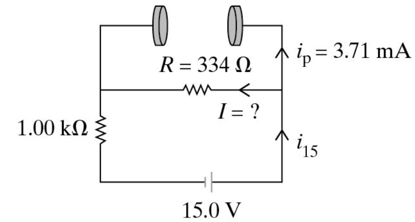

Figure 38.38

(d) We want I. Apply Kirchhoff's rules using the currents shown in Figure 38.38. $i_{15} = I + i$. A counterclockwise path through the lower part of the circuit gives $RI - (1.00 \text{ k}\Omega)i_{15} + 15.0 \text{ V} = 0$. Solve for I using $i = 3.71$ mA and $R = 334\ \Omega$, which gives $I = 8.46$ mA.
(e) We want V_{AC}. $V_{AC} = V_R = RI = (334\ \Omega)(8.46 \text{ mA}) = 2.893$ V.
(f) We want to find R, so that $i = 0$ with $\lambda = 65.0$ nm. If $i = 0$, then V_R is the stopping potential V_0.

$$RI = \frac{hc/\lambda - \phi}{e} \text{ and } I = \frac{\mathcal{E}}{R + 1.00 \text{ k}\Omega}$$

$$\frac{hc/\lambda - \phi}{e} = \frac{R\mathcal{E}}{R + 1.00 \text{ k}\Omega}$$

Using $\mathcal{E} = 15.0$ V, $\phi = 5.10$ eV, and $\lambda = 65.0$ nm, we get $R = 13.8$ kΩ.

EVALUATE: A work function of 5.1 eV is the same as gold and nickel, so it is reasonable.

38.39. IDENTIFY: This problem involves pair production of an electron-positron pair.

SET UP and **EXECUTE:** $\lambda = h/p,\ E = hc/\lambda,\ p = m\gamma v,\ E = m\gamma c^2.$

(a) Energy conservation: $hc/\lambda + Mc^2 = 2myc^2 + M\gamma_M c^2.$

(b) Momentum conservation: $h/\lambda = 2m\gamma v\cos\phi + M\gamma_M V_M$

(c) Eliminate h/λ between the equations in parts (a) and (b) and rearrange to obtain the following:

$$\frac{2m\gamma}{M}\left(1 - \frac{v}{c}\cos\phi\right) + \gamma_M\left(1 - \frac{V_M}{c}\right) = 1.$$

(d) We want V_M if $V_M << c$. If $x << 1$, $(1 + x)^n \approx 1 + nx$. Using $n = -½$ and $x = -(V_M/c)^2$ gives

$$\gamma_M \approx 1 + \left(-\frac{1}{2}\right)\left[-\left(\frac{V_M}{c}\right)^2\right] \approx 1 + \frac{V_M^2}{2c^2} \approx 1.$$

Using this to rewrite the result from part (c) gives

$$\frac{2m\gamma}{M}\left(1 - \frac{v}{c}\cos\phi\right) + 1\frac{V_M}{c} = 1.$$

Solving for V_M gives

$$V_M = \frac{2m\gamma}{M}(c - v\cos\phi).$$

(e) For V_M to be zero, $c - v\cos\phi$ would have to be zero, which is not possible with $v < c$.

(f) We want V_M if M is a proton and $v = 0$. Using the result in part (d) gives

$$V_M = \frac{2m\gamma c}{M} = 327 \text{ Km/s}.$$

(g) We want V_M. Use the result from (d). First use $E = m\gamma c^2$ to find γ.

$$5.00 \text{ MeV} = (0.511 \text{ MeV})\gamma \rightarrow \gamma = 9.785.$$

Now use $v = c\sqrt{1-1/\gamma^2}$ to find v, giving $v = 2.984 \times 10^8$ m/s. Now find V_M for $\phi = 60.0°$ and using the values we just found for v and γ, which gives

$$V_M = \frac{2m\gamma}{M}(c - v\cos\phi) = 1610 \text{ Km/s}.$$

(h) We want the energy E of the incident photon. This energy is equal to the sum of the energy of the electron and positron and the kinetic energy of the proton. The proton is not relativistic, so we have

$$E = 2E_{\text{electron}} + \frac{1}{2}Mv^2.$$

Using E_{electron} = 5.00 MeV and v = 1620 km/s gives E = 2(5.0 MeV) + 0.014 MeV = 10.0 MeV.

EVALUATE: Most of the energy goes to the electron-positron pair.

38.40. IDENTIFY: Follow the derivation of $\lambda' - \lambda = \left(\frac{h}{mc}\right)(1-\cos\phi)$. Apply conservation of energy and conservation of momentum to the collision.

SET UP: Use the coordinate direction specified in the problem.

EXECUTE: **(a)** <u>Momentum</u>: $\vec{\boldsymbol{p}} + \vec{\boldsymbol{P}} = \vec{\boldsymbol{p}}' + \vec{\boldsymbol{P}}' \Rightarrow p - P = -p' - P' \Rightarrow p' = P - (p + P')$.

<u>Energy</u>: $pc + E = p'c + E' = p'c + \sqrt{(P'c)^2 + (mc^2)^2}$

$$\Rightarrow (pc - p'c + E)^2 = (P'c)^2 + (mc^2)^2 = (Pc)^2 + ((p+p')c)^2 - 2P(p+p')c^2 + (mc^2)^2.$$

$$(pc - p'c)^2 + E^2 = E^2 + (pc + p'c)^2 - 2(Pc^2)(p+p') + 2Ec(p-p') - 4pp'c^2 + 2Ec(p-p')$$

$$+2(Pc^2)(p+p') = 0$$

$$\Rightarrow p'(Pc^2 - 2pc^2 - Ec) = p(-Ec - Pc^2)$$

$$\Rightarrow p' = p\frac{Ec + Pc^2}{2pc^2 + Ec - Pc^2} = p\frac{E + Pc}{2pc + (E - Pc)}$$

$$\Rightarrow \lambda' = \lambda\left(\frac{2hc/\lambda + (E - Pc)}{E + Pc}\right) = \lambda\left(\frac{E - Pc}{E + Pc}\right) + \frac{2hc}{E + Pc}$$

$$\Rightarrow \lambda' = \frac{\lambda(E - Pc) + 2hc}{E + Pc}$$

If $E \gg mc^2,\ Pc = \sqrt{E^2 - (mc^2)^2} = E\sqrt{1 - \left(\frac{mc^2}{E}\right)^2} \approx E\left(1 - \frac{1}{2}\left(\frac{mc^2}{E}\right)^2 + \ldots\right)$

$$\Rightarrow E - Pc \approx \tfrac{1}{2}\frac{(mc^2)^2}{E} \Rightarrow \lambda' \approx \frac{\lambda(mc^2)^2}{2E(2E)} + \frac{hc}{E} = \frac{hc}{E}\left(1 + \frac{m^2c^4\lambda}{4hcE}\right).$$

(b) If $\lambda = 10.6\times10^{-6}$ m, $E = 1.00\times10^{10}$ eV $= 1.60\times10^{-9}$ J

$$\Rightarrow \lambda' \approx \frac{hc}{1.60\times10^{-9}\ \text{J}}\left(1 + \frac{(9.11\times10^{-31}\ \text{kg})^2c^4(10.6\times10^{-6}\ \text{m})}{4hc\,(1.6\times10^{-9}\ \text{J})}\right) = (1.24\times10^{-16}\ \text{m})(1 + 56.0)$$

$$= 7.08\times10^{-15}\ \text{m}.$$

(c) These photons are gamma rays. We have taken infrared radiation and converted it into gamma rays! Perhaps useful in nuclear medicine, nuclear spectroscopy, or high energy physics: wherever controlled gamma ray sources might be useful.

EVALUATE: The photon has gained energy from the initial kinetic energy of the electron. Since the photon gains energy, its wavelength decreases.

38.41. IDENTIFY and SET UP: The specific gravity of the tumor is 1, so it has the same density as water, 1000 kg/m^3. If 70 Gy are given in 35 days, the daily treatment is 2 Gy.

EXECUTE: The energy E per cell is

$$E/\text{cell} = \frac{(2\text{ J/kg})\left(\dfrac{1000\text{ kg}}{(100\text{ cm})^3}\right)}{10^8\text{ cells/cm}^3} = (2\times10^{-11}\text{ J/cell})(6\times10^{18}\text{ eV/J}) = 1.2\times10^8\text{ eV/cell} = 120\text{ MeV/cell.}$$

Choice (c) is correct.

EVALUATE: For 35 treatments the total dose would be 120 MeV $\times 35$ = 4200 MeV = 4.2 GeV per cell.

38.42. IDENTIFY and SET UP: Assume that the photon eventually loses all of its energy. Call N the number of ionizations.

EXECUTE: (40 eV)N = 4 MeV = 4 $\times 10^6$ eV $\rightarrow$ $N = 10^5$, so choice (d) is correct.

EVALUATE: This result is an average, since not every ionization would necessarily take 40 eV.

38.43. IDENTIFY and SET UP: For Compton scattering $\lambda' - \lambda = \left(\dfrac{h}{mc}\right)(1-\cos\phi)$. The energy of a photon is $E = hf = hc/\lambda$. The energy gained by the electron is equal to the energy lost by the photon.

EXECUTE: For backscatter, ϕ = 180°, so $\lambda' - \lambda = \left(\dfrac{h}{mc}\right)(1-\cos\phi)$ gives $\lambda' = \lambda + \dfrac{2h}{mc}$.

$E = hc/\lambda = 4$ MeV, so $\lambda = hc/(4\text{ MeV})$. Therefore

$\lambda' = \lambda + \dfrac{2h}{mc}$ = hc/(4 MeV) + 2h/mc = hc[2/(0.511 MeV) + 1/(4 MeV)] = 4.165hc MeV^{-1}.

E_{el} = loss of energy of photon.

E_{el} = $hc/\lambda - hc/\lambda'$ = $\dfrac{hc}{\lambda} - \dfrac{hc}{\lambda'} = hc\left[\dfrac{1}{hc/(4\text{ MeV})} - \dfrac{1}{0.4164hc\text{ MeV}^{-1}}\right]$ = 3.8 MeV. Therefore choice (a) is the correct one.

EVALUATE: Not all electrons would get this much energy because not all the photons would backscatter.

38.44. IDENTIFY and SET UP: The energy of a photon determines whether it is more likely to interact via the photoelectric effect or the Compton effect. The graph in Figure P38.44 shows that at high energies a photon is more likely to interact via the Compton effect, but at low energies it is more likely to interact via the photoelectric effect.

EXECUTE: From the graph we see that a 4-MeV photon has much higher probability of interacting via the Compton effect. But as it loses energy through repeated interactions, it will be more likely to interact via the photoelectric effect. Therefore choice (c) is the best one.

EVALUATE: In Problem 38.42 we saw that a photon can undergo around 10^5 ionization events, and during each of these it loses about 40 eV. Therefore it is reasonable that it would lose significant energy due to these interactions.

38.45. IDENTIFY and SET UP: For bremsstrahlung we have $eV_{AC} = hf_{max}$.

EXECUTE: If the accelerating potential V_{AC} is high, the maximum energy hf_{max} of the emitted photons will be high compared to a low accelerating potential. Thus choice (b) is correct.

EVALUATE: Not all the photons will have this energy, since f_{max} is the largest that the frequency can be.

39

PARTICLES BEHAVING AS WAVES

VP39.2.1. **IDENTIFY:** This problem involves electron diffraction and the de Broglie wavelength.

SET UP: $\lambda = h/p$, $K = p^2/2m$, $a\sin\theta = m\lambda$, $K = eV$.

EXECUTE: **(a)** We want the de Broglie wavelength. First use $K = eV$ and $K = p^2/2m$ to find p, and then use $\lambda = h/p$ to find λ.

$$p = \sqrt{2mK} = \sqrt{2meV}. \lambda = \frac{h}{p} = \frac{h}{\sqrt{2meV}}.$$

Using $V = 69.0$ V gives $\lambda = 0.148$ nm.

(b) We want the minimum angle at which a diffraction maximum occurs. Using $m = 1$, $a\sin\theta = m\lambda$ gives $\theta_{\text{min}} = \arcsin(\lambda/d) = \arcsin(0.148/0.172) = 59.1°$.

EVALUATE: There is no other angle at which a maximum occurs. We can use $K = p^2/2m$ because the electron is nonrelativistic at this energy which is much less than its rest energy of 0.511 MeV.

VP39.2.2. **IDENTIFY:** This problem involves electron diffraction and the de Broglie wavelength.

SET UP: $\lambda = h/p$, $K = p^2/2m$, $d\sin\theta = m\lambda$, $K = eV$.

EXECUTE: **(a)** We want the kinetic energy. $K = eV = e(36.5 \text{ V}) = 36.5 \text{ eV} = 5.85 \times 10^{-18}$ J.

(b) We want the de Broglie wavelength.

$$\lambda = \frac{h}{p} = \frac{h}{\sqrt{2mK}} = 0.202 \text{ nm}.$$

(c) We want the atomic spacing d. $d\sin\theta = m\lambda$ gives $d = (0.203 \text{ nm})/(\sin 48.0°) = 0.273$ nm.

EVALUATE: We can use $K = p^2/2m$ because the electron's speed is much less than c.

VP39.2.3. **IDENTIFY:** This problem involves electron diffraction and the de Broglie wavelength.

SET UP: $\lambda = h/p$, $K = p^2/2m$, $d\sin\theta = m\lambda$, $K = eV$.

EXECUTE: **(a)** We want the de Broglie wavelength. Solving $d\sin\theta = m\lambda$ with $m = 2$ gives

$$\lambda = (0.218 \text{ nm})(\sin 75.0°)/2 = 0.105 \text{ nm}.$$

(b) We want the accelerating voltage V. Solving $eV = K = p^2/2m$ and using $\lambda = h/p$ gives

$$V = \frac{(h/\lambda)^2}{2me} = \frac{h^2}{2me\lambda^2} = \frac{h^2}{2me(0.105 \text{ nm})^2} = 136 \text{ V}.$$

EVALUATE: The electron's kinetic energy is $K = 136$ eV, so it is not relativistic.

VP39.2.4. **IDENTIFY:** This problem involves the de Broglie wavelength of a proton.

SET UP: $\lambda = h/p$, $K = p^2/2m$, $K = eV$.

Execute: **(a)** We want the de Broglie wavelength. Using the given speed gives $\lambda = h/mv = 1.67$ pm.
(b) We want the accelerating voltage V. $eV = K = \frac{1}{2}mv^2$. Solving for V using the known quantities gives $V = 295$ V.
Evaluate: If a proton and electron have comparable speeds, the proton has a *much smaller* de Broglie wavelength because it is much more massive than the electron.

VP39.6.1. **Identify:** The problem involves the energy due to electron transitions in a hypothetical atom.
Set Up and **Execute:** We want the wavelengths of the emitted light in each case. The possible transitions are $5 \to 0$ and $5 \to 2 \to 0$, and $\Delta E = hc/\lambda$.
$\underline{5 \to 0}$: $\Delta E = 5.00\text{ eV} - 0 = 5.00$ eV. $\lambda = hc/\Delta E = hc/(5.00\text{ eV}) = 248$ nm.
$\underline{5 \to 2}$: $\Delta E = 5.00\text{ eV} - 2.00 = 3.00$ eV. $\lambda = hc/\Delta E = hc/(3.00\text{ eV}) = 414$ nm.
$\underline{2 \to 0}$: $\Delta E = 2.00\text{ eV} - 0 = 2.00$ eV. $\lambda = hc/\Delta E = hc/(2.00\text{ eV}) = 620$ nm.
Evaluate: The wavelengths emitted by a gas of this atom would be 248 nm, 414 nm, and 620 nm.

VP39.6.2. **Identify:** The problem involves the energy due to electron transitions in a hypothetical atom.
Set Up: $\Delta E = hc/\lambda$.
Execute: **(a)** $\Delta E_{1\to\text{grd}} = hc/\lambda_1 = hc/(385\text{ nm}) = 3.22\text{ eV}$. Therefore $E_1 = 3.22$ eV relative to ground.
$\Delta E_{2\to 1} = hc/\lambda_2 = hc/(674\text{ nm}) = 1.84\text{ eV}$. Therefore $E_2 = 1.84$ eV relative to E_1. Relative to ground we have $E_2 = 1.84\text{ eV} + 3.22\text{ eV} = 5.06\text{ eV}$.
(b) $\lambda = hc/\Delta E = hc/(5.06\text{ eV}) = 245$ nm.
Evaluate: Note that the energy difference between adjacent levels gets smaller for higher and higher levels.

VP39.6.3. **Identify:** The problem involves electron transitions in a Bohr hydrogen atom.
Set Up: $\Delta E = hc/\lambda$. For the Bohr hydrogen atom, $E_n = -(13.60\text{ eV})/n^2$. We want the energy and wavelength of the emitted photon.
Execute: **(a)** $5 \to 3$: $\Delta E = (-13.60\text{ eV})(1/5^2 - 1/3^2) = 0.967$ eV. $\lambda = hc/\Delta E = hc/(0.967\text{ eV})$ $= 1.28\ \mu$m.
(b) $4 \to 2$: $\Delta E = (-13.60\text{ eV})(1/4^2 - 1/2^2) = 2.55$ eV. $\lambda = hc/\Delta E = hc/(2.55\text{ eV}) = 487$ nm.
(c) $3 \to 1$: $\Delta E = (-13.60\text{ eV})(1/3^2 - 1/1^2) = 12.1$ eV. $\lambda = hc/\Delta E = hc/(12.1\text{ eV}) = 103$ nm.
Evaluate: Note that as the energy difference increases, the wavelength of the emitted photon decreases. This is reasonable because shorter wavelength photons have more energy than long wavelength photons.

VP39.6.4. **Identify:** The problem involves the energy due to electron transitions in a hydrogen atom.
Set Up: $\Delta E = hc/\lambda$. For the Bohr hydrogen atom, $E_n = -(13.60\text{ eV})/n^2$, $K_n = (13.60\text{ eV})/n^2$, and $U_n = -(27.20\text{ eV})/n^2$.
Execute: **(a)** We want the difference in kinetic energy. $\Delta E = K_6 - K_2 = (13.60\text{ eV})(1/6^2 - 1/2^2)$ $= -3.02$ eV.
(b) We want the difference in potential energy. $\Delta U = U_6 - U_2 = (-27.20\text{ eV})(1/6^2 - 1/2^2) = +3.02\text{ eV}$.
(c) We want the wavelength of the photon. $\Delta E = hc/\lambda$ gives $\lambda = hc/\Delta E = hc/(6.04\text{ eV} - 3.02\text{ eV})$ $= 411$ nm.
Evaluate: Check: $\Delta E = K_6 - K_2 = (-13.60\text{ eV})(1/6^2 - 1/2^2) = +3.02\text{ eV}$, as we used in part (c).

VP39.8.1. **Identify:** This problem involves blackbody radiation and the Wien law.
Set Up: $I = \sigma T^4$, Wien law: $\lambda_m = \dfrac{2.90\times 10^{-3}\text{ m}\cdot\text{K}}{T}$.
Execute: **(a)** We want the peak wavelength. Using $T = 3590$ K, the Wien law gives 808 nm. This wavelength is greater than that of visible light, so it is in the *infrared* region.
(b) We want the intensity I. Using $T = 3590$ K, $I = \sigma T^4$ gives 9.42×10^6 W/m^2.

EVALUATE: Betelgeuse is a red giant. It is red because it radiates most of its visible light in the red end of spectrum.

VP39.8.2. **IDENTIFY:** This problem involves blackbody radiation and the Wien law.

SET UP: $I = \sigma T^4$, Wien law: $\lambda_{\text{m}} = \dfrac{2.90\times10^{-3}\ \text{m}\cdot\text{K}}{T}$.

EXECUTE: **(a)** We want the temperature. Solving $I = \sigma T^4$ for T and using $I = 78.0\ \text{MW/m}^2$ gives $T = 6090$ K.

(b) We want the peak wavelength. Using $T = 6090$ in the Wien law gives $\lambda_m = 476$ nm.

(c) This wavelength is in the visible (to humans) part of the electromagnetic spectrum.

EVALUATE: This blackbody would be bluish because the peak wavelength is toward the blue end of the spectrum.

VP39.8.3. **IDENTIFY:** This problem involves blackbody radiation and the Wien law.

SET UP: $I = \sigma T^4$, Wien law: $\lambda_{\text{m}} = \dfrac{2.90\times10^{-3}\ \text{m}\cdot\text{K}}{T}$.

EXECUTE: **(a)** We want the temperature. Using the Wien law with the peak wavelength at 239 nm gives $T = 12{,}100$ K.

(b) We want the power per unit area. Using $I = \sigma T^4$ with $T = 12{,}100$ K gives $I = 1.23 \times 10^9\ \text{W/m}^2 = 1.23\ \text{GW/m}^2$.

EVALUATE: Rigel is a very hot star. Its peak wavelength is in the ultraviolet part of the electromagnetic spectrum.

VP39.8.4 **IDENTIFY:** This problem involves blackbody radiation, the Planck radiation law, and the Wien law.

SET UP: $I = \sigma T^4$, Planck law: $I(\lambda) = \dfrac{2\pi hc^2}{\lambda^5\left(e^{hc/\lambda kT}-1\right)}$, Wien law: $\lambda_{\text{m}} = \dfrac{2.90\times10^{-3}\ \text{m}\cdot\text{K}}{T}$.

EXECUTE: **(a)** We want the peak wavelength. Using the Wien law with $T = 3040$ K gives $\lambda_m = 954$ nm.

(b) We want I. The intensity within the range $\Delta\lambda$ is $I \approx I(\lambda)\Delta\lambda$ if $\Delta\lambda$ is small, as it is in this case. Using the Planck law gives

$$I = I(\lambda)\Delta\lambda = \frac{2\pi hc^2}{\lambda^5\left(e^{hc/\lambda kT}-1\right)}\Delta\lambda.$$

Using $\lambda = 954$ nm, $\Delta\lambda = 12.0$ nm, and $T = 3040$ K gives $I = 40.1\ \text{kW/m}^2$.

EVALUATE: The total intensity the star radiates is $I = \sigma T^4 = 4.84\ \text{MW/m}^2$ at $T = 3040$ K. So the fraction in the 12 nm range is only $(40.1\ \text{kW/m}^2)/(4.84\ \text{MW/m}^2) = 0.83\%$.

39.1. **IDENTIFY** and **SET UP:** $\lambda = \dfrac{h}{p} = \dfrac{h}{mv}$. For an electron, $m = 9.11\times10^{-31}$ kg. For a proton, $m = 1.67\times10^{-27}$ kg.

EXECUTE: **(a)** $\lambda = \dfrac{6.63\times10^{-34}\ \text{J}\cdot\text{s}}{(9.11\times10^{-31}\ \text{kg})(4.70\times10^{6}\ \text{m/s})} = 1.55\times10^{-10}\ \text{m} = 0.155\ \text{nm}.$

(b) λ is proportional to $\dfrac{1}{m}$, so $\lambda_{\text{p}} = \lambda_{\text{e}}\left(\dfrac{m_{\text{e}}}{m_{\text{p}}}\right) = (1.55\times10^{-10}\ \text{m})\left(\dfrac{9.11\times10^{-31}\ \text{kg}}{1.67\times10^{-27}\ \text{kg}}\right) = 8.46\times10^{-14}\ \text{m}.$

EVALUATE: For the same speed the proton has a smaller de Broglie wavelength.

39.2. **IDENTIFY** and **SET UP:** For a photon, $E = \dfrac{hc}{\lambda}$. For an electron or alpha particle, $p = \dfrac{h}{\lambda}$ and $E = \dfrac{p^2}{2m}$, so $E = \dfrac{h^2}{2m\lambda^2}$.

EXECUTE: **(a)** $E = \dfrac{hc}{\lambda} = \dfrac{(4.136\times10^{-15}\ \text{eV}\cdot\text{s})(3.00\times10^{8}\ \text{m/s})}{0.20\times10^{-9}\ \text{m}} = 6.2\ \text{keV}.$

(b) $E = \dfrac{h^2}{2m\lambda^2} = \left(\dfrac{6.63\times10^{-34}\ \text{J}\cdot\text{s}}{0.20\times10^{-9}\ \text{m}}\right)^2 \dfrac{1}{2(9.11\times10^{-31}\ \text{kg})} = 6.03\times10^{-18}\ \text{J} = 38\ \text{eV}.$

(c) $E_{\text{alpha}} = E_{\text{e}}\left(\dfrac{m_{\text{e}}}{m_{\text{alpha}}}\right) = (38\ \text{eV})\left(\dfrac{9.11\times10^{-31}\ \text{kg}}{6.64\times10^{-27}\ \text{kg}}\right) = 5.2\times10^{-3}\ \text{eV}.$

EVALUATE: For a given wavelength a photon has much more energy than an electron, which in turn has more energy than a alpha particle.

39.3. **IDENTIFY:** For a particle with mass, $\lambda = \dfrac{h}{p}$ and $K = \dfrac{p^2}{2m}$.

SET UP: $1\ \text{eV} = 1.60\times10^{-19}\ \text{J}.$

EXECUTE: **(a)** $\lambda = \dfrac{h}{p} \Rightarrow p = \dfrac{h}{\lambda} = \dfrac{(6.63\times10^{-34}\ \text{J}\cdot\text{s})}{(2.80\times10^{-10}\ \text{m})} = 2.37\times10^{-24}\ \text{kg}\cdot\text{m/s}.$

(b) $K = \dfrac{p^2}{2m} = \dfrac{(2.37\times10^{-24}\ \text{kg}\cdot\text{m/s})^2}{2(9.11\times10^{-31}\ \text{kg})} = 3.08\times10^{-18}\ \text{J} = 19.3\ \text{eV}.$

EVALUATE: This wavelength is on the order of the size of an atom. This energy is on the order of the energy of an electron in an atom.

39.4. **IDENTIFY:** For a particle with mass, $\lambda = \dfrac{h}{p}$ and $E = \dfrac{p^2}{2m}$.

SET UP: $1\ \text{eV} = 1.60\times10^{-19}\ \text{J}.$

EXECUTE: $\lambda = \dfrac{h}{p} = \dfrac{h}{\sqrt{2mE}} = \dfrac{(6.63\times10^{-34}\ \text{J}\cdot\text{s})}{\sqrt{2(6.64\times10^{-27}\ \text{kg})\,(4.20\times10^{6}\ \text{eV})\,(1.60\times10^{-19}\ \text{J/eV})}} = 7.02\times10^{-15}\ \text{m}.$

EVALUATE: This wavelength is on the order of the size of a nucleus.

39.5. **IDENTIFY** and **SET UP:** The de Broglie wavelength is $\lambda = \dfrac{h}{p} = \dfrac{h}{mv}$.

EXECUTE: The de Broglie wavelength is the same for the proton and the electron, so $\dfrac{h}{m_{\text{e}}v_{\text{e}}} = \dfrac{h}{m_{\text{p}}v_{\text{p}}}$.

$v_{\text{p}} = v_{\text{e}}(m_{\text{e}}/m_{\text{p}}) = (8.00\times10^{6}\ \text{m/s})[(9.109\times10^{-31}\ \text{kg})/(1.6726\times10^{-27}\ \text{kg})] = 4360\ \text{m/s} = 4.36\ \text{km/s}.$

EVALUATE: The proton and electron have the same de Broglie wavelength and the same momentum, but very different speeds because $m_{\text{p}} >> m_{\text{e}}$.

39.6. **IDENTIFY:** This problem is about the de Broglie wavelength.

SET UP: $\lambda = h/p$, $1\ \text{eV} = 1.60\times10^{-19}\ \text{J}$. An electron has mass 9.11×10^{-31} kg.

EXECUTE: **(a)** For a nonrelativistic particle, $K = \dfrac{p^2}{2m}$, so $\lambda = \dfrac{h}{p} = \dfrac{h}{\sqrt{2Km}}$.

(b) $(6.63\times10^{-34}\ \text{J}\cdot\text{s})/\sqrt{2(800\ \text{eV})(1.60\times10^{-19}\ \text{J/eV})(9.11\times10^{-31}\ \text{kg})} = 4.34\times10^{-11}\ \text{m}.$

EVALUATE: The de Broglie wavelength decreases when the kinetic energy of the particle increases.

39.7. **IDENTIFY:** This problem is about the de Broglie wavelength.

SET UP: $\lambda = h/p$, $K = p^2/2m$, $p = m\gamma v$, $K = mc^2(\gamma - 1)$, $v = c\sqrt{1 - 1/\gamma^2}$. We want the de Broglie wavelength in each case.

EXECUTE: **(a)** $\lambda = h/p = h/(50.0\ \text{kg})(2.0\ \text{m/s}) = 6.6\times10^{-36}\ \text{m}.$

(b) The kinetic energy of the electron (2.0 MeV) is considerably greater than the rest energy (0.511 MeV) of the electron, so we must use the relativistic equations. $K = mc^2(\gamma - 1)$ gives $2.0\text{ MeV} = (0.511\text{ MeV})(\gamma - 1)$, so $\gamma = 4.914$. Now find the wavelength. Combining $\lambda = h/p$, $p = m\gamma v$, and $v = c\sqrt{1 - 1/\gamma^2}$ gives $\lambda = \dfrac{h}{mc\sqrt{\gamma^2 - 1}}$. Using $\gamma = 4.914$ gives $v = 5.0\times10^{-13}$ m/s.

(c) This electron is not relativistic, so we use $K = p^2/2m$. Solving for v and using $\lambda = h/p$ gives $\lambda = \dfrac{h}{\sqrt{2mK}}$. Using $K = 20\text{ eV} = 3.20\times10^{-18}$ J, we get $\lambda = 0.27$ nm.

EVALUATE: From part (a) we see that for ordinary everyday objects, the de Broglie wavelength is extremely small, much less than for things like electrons.

39.8. IDENTIFY and SET UP: Combining $E = \gamma mc^2$ and $E^2 = (mc^2)^2 + (pc)^2$ gives $p = mc\sqrt{\gamma^2 - 1}$.

EXECUTE: (a) $\lambda = \dfrac{h}{p} = (h/mc)/\sqrt{\gamma^2 - 1} = 4.43\times10^{-12}$ m. (The incorrect nonrelativistic calculation gives 5.05×10^{-12} m.)

(b) $(h/mc)/\sqrt{\gamma^2 - 1} = 7.07\times10^{-13}$ m.

EVALUATE: The de Broglie wavelength decreases when the speed increases.

39.9. IDENTIFY and SET UP: Use $\lambda = h/p$.

EXECUTE: $\lambda = \dfrac{h}{p} = \dfrac{h}{mv} = \dfrac{6.626\times10^{-34}\text{ J}\cdot\text{s}}{(5.00\times10^{-3}\text{ kg})(340\text{ m/s})} = 3.90\times10^{-34}$ m.

EVALUATE: This wavelength is extremely short; the bullet will not exhibit wavelike properties.

39.10. IDENTIFY: Apply conservation of energy to relate the potential difference to the speed of the electrons.

SET UP: The mass of an electron is $m = 9.11\times10^{-31}$ kg. The energy of a photon is $E = \dfrac{hc}{\lambda}$.

EXECUTE: (a) $\lambda = h/mv \to v = h/m\lambda$. Energy conservation gives $e\Delta V = \frac{1}{2}mv^2$.

$$\Delta V = \frac{mv^2}{2e} = \frac{m\left(\dfrac{h}{m\lambda}\right)^2}{2e} = \frac{h^2}{2em\lambda^2} = \frac{(6.626\times10^{-34}\text{ J}\cdot\text{s})^2}{2(1.60\times10^{-19}\text{ C})(9.11\times10^{-31}\text{ kg})\,(0.220\times10^{-9}\text{ m})^2} = 31.1\text{ V}.$$

(b) $E_{\text{photon}} = hf = \dfrac{hc}{\lambda} = \dfrac{(6.626\times10^{-34}\text{ J}\cdot\text{s})\,(3.00\times10^8\text{ m/s})}{0.220\times10^{-9}\text{ m}} = 9.035\times10^{-16}$ J. $e\Delta V = K = E_{\text{photon}}$ and

$$\Delta V = \frac{E_{\text{photon}}}{e} = \frac{9.035\times10^{-16}\text{ J}}{1.60\times10^{-19}\text{ C}} = 5650\text{ V}.$$

EVALUATE: The electron in part (b) has wavelength $\lambda = \dfrac{h}{p} = \dfrac{h}{\sqrt{2mE}}$

$= \dfrac{6.626\times10^{-34}\text{ J}\cdot\text{s}}{\sqrt{2(9.11\times10^{-31}\text{ kg})(9.035\times10^{-16}\text{ J})}} = 0.0163$ nm, which is much shorter than the 0.220-nm wavelength of a photon of the same energy.

39.11. IDENTIFY: The acceleration gives momentum to the electrons. We can use this momentum to calculate their de Broglie wavelength.

SET UP: The kinetic energy K of the electron is related to the accelerating voltage V by $K = eV$. For an electron $E = \frac{1}{2}mv^2 = \dfrac{p^2}{2m}$ and $\lambda = \dfrac{h}{p}$. For a photon $E = \dfrac{hc}{\lambda}$.

EXECUTE: **(a)** For an electron $p=\dfrac{h}{\lambda}=\dfrac{6.63\times10^{-34}\text{ J}\cdot\text{s}}{5.00\times10^{-9}\text{ m}}=1.33\times10^{-25}\text{ kg}\cdot\text{m/s}$ and

$E=\dfrac{p^2}{2m}=\dfrac{(1.33\times10^{-25}\text{ kg}\cdot\text{m/s})^2}{2(9.11\times10^{-31}\text{ kg})}=9.71\times10^{-21}\text{ J}.$ $V=\dfrac{K}{e}=\dfrac{9.71\times10^{-21}\text{ J}}{1.60\times10^{-19}\text{ C}}=0.0607\text{ V}.$ The electrons would have kinetic energy 0.0607 eV.

(b) $E=\dfrac{hc}{\lambda}=\dfrac{1.24\times10^{-6}\text{ eV}\cdot\text{m}}{5.00\times10^{-9}\text{ m}}=248\text{ eV}.$

(c) $E=9.71\times10^{-21}\text{ J}$, so $\lambda=\dfrac{hc}{E}=\dfrac{(6.63\times10^{-34}\text{ J}\cdot\text{s})(3.00\times10^{8}\text{ m/s})}{9.71\times10^{-21}\text{ J}}=20.5\ \mu\text{m}.$

EVALUATE: If they have the same wavelength, the photon has vastly more energy than the electron.

39.12. **IDENTIFY:** The electrons behave like waves and are diffracted by the slit.

SET UP: We use conservation of energy to find the speed of the electrons, and then use this speed to find their de Broglie wavelength, which is $\lambda=h/mv$. Finally we know that the first dark fringe for single-slit diffraction occurs when $a\sin\theta=\lambda$. The relativistic kinetic energy is $K=(\gamma-1)mc^2$.

EXECUTE: **(a)** The electrons gain kinetic energy K as they are accelerated through a potential difference V, so $eV=K=(\gamma-1)mc^2$. The potential difference is 0.100 kV, so eV = 0.100 keV. Therefore

$$eV=K=(\gamma-1)mc^2=0.100\text{ keV}.$$

Solving for γ and using the fact that the rest energy of an electron is 0.511 MeV, we have

$$\gamma-1=(0.100\text{ keV})/(0.511\text{ MeV})=(0.100\text{ keV})/(511\text{ keV})=1.96\times10^{-4}$$

so $\gamma<<1$ which means that we do not have to use special relativity.

(b) Use energy conservation to find the speed of the electron: $\frac{1}{2}mv^2=eV$.

$$v=\sqrt{\frac{2eV}{m}}=\sqrt{\frac{2(1.60\times10^{-19}\text{ C})(100\text{ V})}{9.11\times10^{-31}\text{ kg}}}=5.93\times10^{6}\text{ m/s}.$$

Now find the de Broglie wavelength:

$$\lambda=\frac{h}{mv}=\frac{6.626\times10^{-34}\text{ J}\cdot\text{s}}{(9.11\times10^{-31}\text{ kg})(5.93\times10^{6}\text{ m/s})}=1.23\times10^{-10}\text{ m}=0.123\text{ nm}.$$

For the first single-slit dark fringe, we have $a\sin\theta=\lambda$, which gives

$$a=\frac{\lambda}{\sin\theta}=\frac{1.23\times10^{-10}\text{ m}}{\sin(14.6°)}=4.88\times10^{-10}\text{ m}=0.488\text{ nm}.$$

EVALUATE: The slit width is around 4 times the de Broglie wavelength of the electron, and both are much smaller than the wavelength of visible light.

39.13. **IDENTIFY:** The intensity maxima are located by $d\sin\theta=m\lambda$. Use $\lambda=\dfrac{h}{p}$ for the wavelength of the neutrons. For a particle, $p=\sqrt{2mE}$.

SET UP: For a neutron, $m=1.675\times10^{-27}$ kg.

EXECUTE: For $m=1$, $\lambda=d\sin\theta=\dfrac{h}{\sqrt{2mE}}$.

$$E=\frac{h^2}{2md^2\sin^2\theta}=\frac{(6.63\times10^{-34}\text{ J}\cdot\text{s})^2}{2(1.675\times10^{-27}\text{ kg})(9.10\times10^{-11}\text{ m})^2\sin^2(28.6°)}=6.91\times10^{-20}\text{ J}=0.432\text{ eV}.$$

EVALUATE: The neutrons have $\lambda=0.0436$ nm, comparable to the atomic spacing.

39.14. **IDENTIFY:** $\lambda = h/p$. Conservation of energy gives $eV = K = \dfrac{p^2}{2m}$, where V is the accelerating voltage.

SET UP: The electron mass is 9.11×10^{-31} kg and the proton mass is 1.67×10^{-27} kg.

EXECUTE: **(a)** $eV = K = \dfrac{p^2}{2m} = \dfrac{(h/\lambda)^2}{2m}$, so $V = \dfrac{(h/\lambda)^2}{2me} = 419$ V.

(b) The voltage is reduced by the ratio of the particle masses, $(419\text{ V})\dfrac{9.11\times10^{-31}\text{ kg}}{1.67\times10^{-27}\text{ kg}} = 0.229$ V.

EVALUATE: $\lambda = \dfrac{h}{p} = \dfrac{h}{\sqrt{2mE}}$. For the same λ, particles of greater mass have smaller E, so a smaller accelerating voltage is needed for protons.

39.15. **IDENTIFY:** We are comparing the wavelengths of a photon and an electron having the same energy.
SET UP: $\lambda = h/p$, $E = hc/\lambda$. We want the wavelengths.

EXECUTE: **(a)** Photon: $\lambda = \dfrac{hc}{E} = \dfrac{(4.136\times10^{-15}\text{ eV}\cdot\text{s})c}{6.00\text{ eV}} = 207$ nm.

(b) Electron: Combine $\lambda = h/p$ and $K = p^2/2m$ to get $\lambda = \dfrac{h}{\sqrt{2mK}}$. Using $K = 6.00\text{ eV} = 9.60\times10^{-19}$ J gives $\lambda = 0.501$ nm.

(c) The photon has a *much* longer wavelength than the electron.
EVALUATE: Notice that if a particle has the same kinetic energy as the energy of a photon, the particle has a much shorter wavelength.

39.16. **IDENTIFY:** We are comparing the energy of a photon and an electron having the same wavelength of 500 nm.

SET UP: $\lambda = h/p$, $E = hc/\lambda$, $K = p^2/2m$. We want the energy of each one.

EXECUTE: **(a)** Photon: Using the 500 nm wavelength gives $E = hc/\lambda = 2.48$ eV.

Electron: Combine $\lambda = h/p$ and $K = p^2/2m$ to get $K = \dfrac{p^2}{2m} = \dfrac{(h/\lambda)^2}{2m}$. Using 500 nm for the wavelength gives $K = 9.639\times10^{-25}\text{ J} = 6.02\times10^{-6}$ eV.

(b) The photon has much more energy than the electron.
EVALUATE: Note that of a photon and particle have the same wavelength, the photon has much more energy than the particle.

39.17. **(a) IDENTIFY:** If the particles are treated as point charges, $U = \dfrac{1}{4\pi\epsilon_0}\dfrac{q_1q_2}{r}$.

SET UP: $q_1 = 2e$ (alpha particle); $q_2 = 82e$ (lead nucleus); r is given so we can solve for U.

EXECUTE: $U = (8.987\times10^9\text{ N}\cdot\text{m}^2/\text{C}^2)\dfrac{(2)(82)(1.602\times10^{-19}\text{ C})^2}{6.50\times10^{-14}\text{ m}} = 5.82\times10^{-13}$ J

$$U = 5.82\times10^{-13}\text{ J }(1\text{ eV}/1.602\times10^{-19}\text{ J}) = 3.63\times10^6\text{ eV} = 3.63\text{ MeV}$$

(b) IDENTIFY: Apply conservation of energy: $K_1 + U_1 = K_2 + U_2$.

SET UP: Let point 1 be the initial position of the alpha particle and point 2 be where the alpha particle momentarily comes to rest. Alpha particle is initially far from the lead nucleus implies $r_1 \approx \infty$ and $U_1 = 0$. Alpha particle stops implies $K_2 = 0$.

EXECUTE: Conservation of energy thus says $K_1 = U_2 = 5.82\times10^{-13}\ \text{J} = 3.63\ \text{MeV}.$

(c) $K = \frac{1}{2}mv^2,$ so $v = \sqrt{\dfrac{2K}{m}} = \sqrt{\dfrac{2(5.82\times10^{-13}\ \text{J})}{6.64\times10^{-27}\ \text{kg}}} = 1.32\times10^7\ \text{m/s}.$

EVALUATE: $v/c = 0.044,$ so it is ok to use the nonrelativistic expression to relate K and v. When the alpha particle stops, all its initial kinetic energy has been converted to electrostatic potential energy.

39.18. IDENTIFY: The kinetic energy of the alpha particle is all converted to electrical potential energy at closest approach. The force on the alpha particle is the electrical repulsion of the nucleus.

SET UP: The electrical potential energy of the system is $U = \dfrac{1}{4\pi\epsilon_0}\dfrac{q_1q_2}{r}.$

EXECUTE: **(a)** Equating the initial kinetic energy and the final potential energy and solving for the separation radius r gives

$$r = \frac{1}{4\pi\epsilon_0}\frac{(92e)(2e)}{K} = \frac{1}{4\pi\epsilon_0}\frac{(184)(1.60\times10^{-19}\ \text{C})^2}{(4.78\times10^6\ \text{eV})(1.60\times10^{-19}\ \text{J/eV})} = 5.54\times10^{-14}\ \text{m}.$$

(b) The above result may be substituted into Coulomb's law. Alternatively, the relation between the magnitude of the force and the magnitude of the potential energy in a Coulomb field is $F = \dfrac{|U|}{r}.$

$|U| = K,$ so $F = \dfrac{K}{r} = \dfrac{(4.78\times10^6\ \text{eV})(1.6\times10^{-19}\ \text{J/ev})}{(5.54\times10^{-14}\ \text{m})} = 13.8\ \text{N}.$

EVALUATE: The result in part (a) is comparable to the radius of a large nucleus, so it is reasonable. The force in part (b) is around 3 pounds, which is large enough to be easily felt by a person.

39.19. IDENTIFY and SET UP: Use the energy to calculate n for this state. Then use the Bohr equation, $L = n\hbar,$ to calculate L.

EXECUTE: $E_n = -(13.6\ \text{eV})/n^2,$ so this state has $n = \sqrt{13.6/1.51} = 3.$ In the Bohr model, $L = n\hbar,$ so for this state $L = 3\hbar = 3.16\times10^{-34}\ \text{kg}\cdot\text{m}^2/\text{s}.$

EVALUATE: We will find in Section 41.1 that the modern quantum mechanical description gives a different result.

39.20. IDENTIFY and SET UP: For a hydrogen atom $E_n = -\dfrac{13.6\ \text{eV}}{n^2}.$ $\Delta E = \dfrac{hc}{\lambda},$ where ΔE is the magnitude of the energy change for the atom and λ is the wavelength of the photon that is absorbed or emitted.

EXECUTE: $\Delta E = E_3 - E_1 = -(13.6\ \text{eV})\left(\dfrac{1}{3^2} - \dfrac{1}{1^2}\right) = +12.09\ \text{eV}.$

$\lambda = \dfrac{hc}{\Delta E} = \dfrac{(4.136\times10^{-15}\ \text{eV}\cdot\text{s})(3.00\times10^8\ \text{m/s})}{12.09\ \text{eV}} = 102.6\ \text{nm},$ which rounds to 103 nm.

The frequency is $f = \dfrac{c}{\lambda} = \dfrac{2.998\times10^8\ \text{m/s}}{102.6\times10^{-9}\ \text{m}} = 2.92\times10^{15}\ \text{Hz}.$

EVALUATE: This photon is in the ultraviolet region of the electromagnetic spectrum.

39.21. IDENTIFY: The force between the electron and the nucleus in Be^{3+} is $F = \dfrac{1}{4\pi\epsilon_0}\dfrac{Ze^2}{r^2},$ where $Z = 4$ is the nuclear charge. All the equations for the hydrogen atom apply to Be^{3+} if we replace e^2 by Ze^2.

(a) SET UP: Modify the energy equation for hydrogen, $E_n = -\dfrac{1}{\epsilon_0^2}\dfrac{me^4}{8n^2h^2}$ by replacing e^2 with Ze^2.

EXECUTE: $E_n = -\frac{1}{\epsilon_0^2}\frac{me^4}{8n^2h^2}$ (hydrogen) becomes

$$E_n = -\frac{1}{\epsilon_0^2}\frac{m(Ze^2)^2}{8n^2h^2} = Z^2\left(-\frac{1}{\epsilon_0^2}\frac{me^4}{8n^2h^2}\right) = Z^2\left(-\frac{13.60\text{ eV}}{n^2}\right)(\text{for Be}^{3+}).$$

The ground-level energy of Be^{3+} is $E_1 = 16\left(-\frac{13.60\text{ eV}}{1^2}\right) = -218\text{ eV}$.

EVALUATE: The ground-level energy of Be^{3+} is $Z^2 = 16$ times the ground-level energy of H.

(b) SET UP: The ionization energy is the energy difference between the $n \to \infty$ level energy and the $n = 1$ level energy.

EXECUTE: The $n \to \infty$ level energy is zero, so the ionization energy of Be^{3+} is 218 eV.

EVALUATE: This is 16 times the ionization energy of hydrogen.

(c) SET UP: $\frac{1}{\lambda} = R\left(\frac{1}{n_1^2} - \frac{1}{n_2^2}\right)$ just as for hydrogen but now R has a different value.

EXECUTE: $R_{\text{H}} = \frac{me^4}{8\epsilon_0^2 h^3 c} = 1.097\times10^7\text{ m}^{-1}$ for hydrogen becomes $R_{\text{Be}} = Z^2\frac{me^4}{8\epsilon_0^2 h^3 c}$

$= 16(1.097\times10^7\text{ m}^{-1}) = 1.755\times10^8\text{ m}^{-1}$ for Be^{3+}.

For $n = 2$ to $n = 1$, $\frac{1}{\lambda} = R_{\text{Be}}\left(\frac{1}{1^2} - \frac{1}{2^2}\right) = 3R_{\text{Be}}/4$.

$$\lambda = 4/(3R_{\text{Be}}) = 4/(3(1.755\times10^8\text{ m}^{-1})) = 7.60\times10^{-9}\text{ m} = 7.60\text{ nm}.$$

EVALUATE: This wavelength is smaller by a factor of 16 compared to the wavelength for the corresponding transition in the hydrogen atom.

(d) SET UP: Modify the Bohr equation for hydrogen, $r_n = \epsilon_0\frac{n^2h^2}{\pi me^2}$, by replacing e^2 with Ze^2.

EXECUTE: $r_n = \epsilon_0\frac{n^2h^2}{\pi m(Ze^2)}$ (Be^{3+}).

EVALUATE: For a given n the orbit radius for Be^{3+} is smaller by a factor of $Z = 4$ compared to the corresponding radius for hydrogen.

39.22. IDENTIFY and SET UP: In the Bohr model for hydrogen, the energy levels are $E_n = -\frac{13.60\text{ eV}}{n^2}$ and the orbital radii are $r_n = n^2a_0$.

EXECUTE: **(a)** $E_2 - E_1 = -(13.6\text{ eV})(1/2^2 - 1/1^2) = 10.20\text{ eV}$.

$E_{10} - E_9 = -(13.6\text{ eV})(1/10^2 - 1/9^2) = 0.03190\text{ eV}$.

(b) $E_{n+1} - E_n = -(13.6\text{ eV})\left[\frac{1}{(n+1)^2} - \frac{1}{n^2}\right] = -(13.6\text{ eV})\left[\frac{n^2-(n+1)^2}{n^2(n+1)^2}\right] = (13.6\text{ eV})\left[\frac{2n+1}{n^2(n+1)^2}\right]$.

As n gets very large, the factor in brackets approaches $2n/n^4 = 2/n^3$, so the entire quantity approaches $(13.6\text{ eV})(2/n^3) = (27.2\text{ eV})/n^3$.

(c) $r_{n+1} - r_n = a_0\left[(n+1)^2 - n^2\right] = a_0(n^2 + 2n + 1 - n^2) = (2n+1)a_0$. As n gets larger, $2n + 1$ gets larger, so the radial distance between adjacent orbits increases.

EVALUATE: As n gets large, the energy difference between adjacent shells gets small, but the radial distance between adjacent shells gets large. In other words, the orbits get progressively farther apart, but their energy gets closer together.

39.23. **IDENTIFY:** Apply the equations for v_n and r_n: $v_n = \dfrac{e^2}{2\epsilon_0 nh}$, $r_n = \epsilon_0 \dfrac{n^2h^2}{\pi me^2}$.

SET UP: The orbital period for state n is the circumference of the orbit divided by the orbital speed.

EXECUTE: **(a)** $v_n = \dfrac{1}{\epsilon_0}\dfrac{e^2}{2nh}: n = 1 \Rightarrow v_1 = \dfrac{(1.602\times10^{-19}\text{ C})^2}{\epsilon_0\, 2\,(6.626\times10^{-34}\text{ J}\cdot\text{s})} = 2.19\times10^6$ m/s.

$n = 2 \Rightarrow v_2 = \dfrac{v_1}{2} = 1.09\times10^6$ m/s. $n = 3 \Rightarrow v_3 = \dfrac{v_1}{3} = 7.27\times10^5$ m/s.

(b) Orbital period $= \dfrac{2\pi r_n}{v_n} = \dfrac{2\epsilon_0\, n^2h^2/me^2}{1/\epsilon_0 \cdot e^2/2nh} = \dfrac{4\epsilon_0^2\, n^3h^3}{me^4}$.

$n = 1 \Rightarrow T_1 = \dfrac{4\epsilon_0^2\,(6.626\times10^{-34}\text{ J}\cdot\text{s})^3}{(9.11\times10^{-31}\text{ kg})(1.602\times10^{-19}\text{ C})^4} = 1.53\times10^{-16}$ s

$n = 2\text{: } T_2 = T_1(2)^3 = 1.22\times10^{-15}$ s. $n = 3\text{: } T_3 = T_1(3)^3 = 4.13\times10^{-15}$ s.

(c) number of orbits $= \dfrac{1.0\times10^{-8}\text{ s}}{1.22\times10^{-15}\text{ s}} = 8.2\times10^6$.

EVALUATE: The orbital speed is proportional to $1/n$, the orbital radius is proportional to n^2, and the orbital period is proportional to n^3.

39.24. **IDENTIFY:** This problem deals with the Bohr model of the atom.

SET UP: $K = p^2/2m$, $K_n = (13.60\text{ eV})/n^2$, $L_n = nh/2\pi$.

EXECUTE: **(a)** We want the kinetic energy. Using $K = p^2/2m$ with the given momentum, we get $K = 1.52$ eV.

(b) We want the angular momentum. First find n using the result from part (a). Solve the equation $K_n = (13.60\text{ eV})/n^2$ for n, giving $n = \sqrt{\dfrac{13.60\text{ eV}}{1.52\text{ eV}}} = 3$. Now find L. $L = 3(h/2\pi) = 3.16\times10^{-34}\text{ kg}\cdot\text{m}^2/\text{s}$.

(c) $n = 3$, as shown above.

EVALUATE: The electron is in the second excited state.

39.25. **IDENTIFY** and **SET UP:** The ionization threshold is at $E = 0$. The energy of an absorbed photon equals the energy gained by the atom and the energy of an emitted photon equals the energy lost by the atom.

EXECUTE: **(a)** $\Delta E = 0 - (-20\text{ eV}) = 20$ eV.

(b) When the atom in the $n = 1$ level absorbs an 18-eV photon, the final level of the atom is $n = 4$. The possible transitions from $n = 4$ and corresponding photon energies are $n = 4 \to n = 3$, 3 eV; $n = 4 \to n = 2$, 8 eV; $n = 4 \to n = 1$, 18 eV. Once the atom has gone to the $n = 3$ level, the following transitions can occur: $n = 3 \to n = 2$, 5 eV; $n = 3 \to n = 1$, 15 eV. Once the atom has gone to the $n = 2$ level, the following transition can occur: $n = 2 \to n = 1$, 10 eV. The possible energies of emitted photons are: 3 eV, 5 eV, 8 eV, 10 eV, 15 eV, and 18 eV.

(c) There is no energy level 8 eV higher in energy than the ground state, so the photon cannot be absorbed.

(d) The photon energies for $n = 3 \to n = 2$ and for $n = 3 \to n = 1$ are 5 eV and 15 eV. The photon energy for $n = 4 \to n = 3$ is 3 eV. The work function must have a value between 3 eV and 5 eV.

EVALUATE: The atom has discrete energy levels, so the energies of emitted or absorbed photons have only certain discrete energies.

39.26. **IDENTIFY:** We are investigating a positronium atom using the Bohr model.

SET UP and **EXECUTE:** **(a)** We want the reduced mass m_r.

$$m_r = \frac{m_1 m_2}{m_1 + m_2} = \frac{m^2}{m+m} = m/2.$$

(b) We want r. In the ground state, $n = 1$.

$$r_n = \epsilon_0 \frac{n^2 h^2}{\pi m_r e^2} = 2a_0 = 0.106 \text{ nm}.$$

(c) We want E_1. Using $m = m_r$ and $n = 1$ gives

$$E_n = -\frac{me^2}{\epsilon_0^2 \, 8n^2 h^2} = \frac{1}{2}(-13.60 \text{ eV}) = -6.80 \text{ eV}.$$

(d) We want the wavelength. The energy E is the energy difference between the levels. Find E and then solve for the wavelength.

$$E = \frac{hc}{\lambda} = (-6.80 \text{ eV})\left(\frac{1}{3^2} - \frac{1}{2^2}\right) = 0.9444 \text{ eV}.$$

This gives $\lambda = 1310$ nm.

EVALUATE: The magnitude of the ground state energy for positronium is less than that of hydrogen. Therefore the photons emitted during transitions in positronium have less energy (and hence longer wavelength) than in comparable transition in hydrogen.

39.27. **IDENTIFY** and **SET UP:** The wavelength of the photon is related to the transition energy $E_i - E_f$ of the atom by $E_i - E_f = \dfrac{hc}{\lambda}$ where $hc = 1.240 \times 10^{-6} \text{ eV} \cdot \text{m}$.

EXECUTE: **(a)** The minimum energy to ionize an atom is when the upper state in the transition has $E = 0$, so $E_1 = -17.50$ eV. For $n = 5 \to n = 1$, $\lambda = 73.86$ nm and $E_5 - E_1 = \dfrac{1.240 \times 10^{-6} \text{ eV} \cdot \text{m}}{73.86 \times 10^{-9} \text{ m}}$ $= 16.79$ eV. $E_5 = -17.50 \text{ eV} + 16.79 \text{ eV} = -0.71$ eV. For $n = 4 \to n = 1$, $\lambda = 75.63$ nm and $E_4 = -1.10$ eV. For $n = 3 \to n = 1$, $\lambda = 79.76$ nm and $E_3 = -1.95$ eV. For $n = 2 \to n = 1$, $\lambda = 94.54$ nm and $E_2 = -4.38$ eV.

(b) $E_i - E_f = E_4 - E_2 = -1.10 \text{ eV} - (-4.38 \text{ eV}) = 3.28$ eV and $\lambda = \dfrac{hc}{E_i - E_f} = \dfrac{1.240 \times 10^{-6} \text{ eV} \cdot \text{m}}{3.28 \text{ eV}}$ $= 378$ nm.

EVALUATE: The $n = 4 \to n = 2$ transition energy is smaller than the $n = 4 \to n = 1$ transition energy so the wavelength is longer. In fact, this wavelength is longer than for any transition that ends in the $n = 1$ state.

39.28. **IDENTIFY** and **SET UP:** For the Lyman series the final state is $n = 1$ and the wavelengths are given by $\dfrac{1}{\lambda} = R\left(\dfrac{1}{1^2} - \dfrac{1}{n^2}\right)$, $n = 2, 3, \ldots$. For the Paschen series the final state is $n = 3$ and the wavelengths are given by $\dfrac{1}{\lambda} = R\left(\dfrac{1}{3^2} - \dfrac{1}{n^2}\right)$, $n = 4, 5, \ldots$. $R = 1.097 \times 10^7 \text{ m}^{-1}$. The longest wavelength is for the smallest n and the shortest wavelength is for $n \to \infty$.

EXECUTE: Lyman: Longest: $\dfrac{1}{\lambda} = R\left(\dfrac{1}{1^2} - \dfrac{1}{2^2}\right) = \dfrac{3R}{4}$. $\lambda = \dfrac{4}{3(1.097 \times 10^7 \text{ m}^{-1})} = 121.5$ nm.

Shortest: $\dfrac{1}{\lambda} = R\left(\dfrac{1}{1^2} - \dfrac{1}{\infty^2}\right) = R$. $\lambda = \dfrac{1}{1.097 \times 10^7 \text{ m}^{-1}} = 91.16$ nm.

Paschen: Longest: $\frac{1}{\lambda}=R\left(\frac{1}{3^2}-\frac{1}{4^2}\right)=\frac{7R}{144}$. $\lambda=\frac{144}{7(1.097\times10^7\ \text{m}^{-1})}=1875\ \text{nm}$.

Shortest: $\frac{1}{\lambda}=R\left(\frac{1}{3^2}-\frac{1}{\infty^2}\right)=\frac{R}{9}$. $\lambda=\frac{9}{1.097\times10^7\ \text{m}^{-1}}=820\ \text{nm}$.

EVALUATE: The Lyman series is in the ultraviolet. The Paschen series is in the infrared.

39.29. IDENTIFY: Apply conservation of energy to the system of atom and photon.

SET UP: The energy of a photon is $E_\gamma=\frac{hc}{\lambda}$.

EXECUTE: **(a)** $E_\gamma=\frac{hc}{\lambda}=\frac{(6.63\times10^{-34}\ \text{J}\cdot\text{s})(3.00\times10^8\ \text{m/s})}{8.60\times10^{-7}\ \text{m}}=2.31\times10^{-19}\ \text{J}=1.44\ \text{eV}$. So the internal energy of the atom increases by $1.44\ \text{eV}$ to $E=-6.52\ \text{eV}+1.44\ \text{eV}=-5.08\ \text{eV}$.

(b) $E_\gamma=\frac{hc}{\lambda}=\frac{(6.63\times10^{-34}\ \text{J}\cdot\text{s})(3.00\times10^8\ \text{m/s})}{4.20\times10^{-7}\ \text{m}}=4.74\times10^{-19}\ \text{J}=2.96\ \text{eV}$. So the final internal energy of the atom decreases to $E=-2.68\ \text{eV}-2.96\ \text{eV}=-5.64\ \text{eV}$.

EVALUATE: When an atom absorbs a photon the energy of the atom increases. When an atom emits a photon the energy of the atom decreases.

39.30. IDENTIFY and **SET UP:** Balmer's formula is $\frac{1}{\lambda}=R\left(\frac{1}{2^2}-\frac{1}{n^2}\right)$. For the H_γ spectral line $n=5$. Once we have λ, calculate f from $f=c/\lambda$ and E using $E=hf$.

EXECUTE: **(a)** $\frac{1}{\lambda}=R\left(\frac{1}{2^2}-\frac{1}{5^2}\right)=R\left(\frac{25-4}{100}\right)=R\left(\frac{21}{100}\right)$.

Thus $\lambda=\frac{100}{21R}=\frac{100}{21(1.097\times10^7)}\ \text{m}=4.341\times10^{-7}\ \text{m}=434.1\ \text{nm}$.

(b) $f=\frac{c}{\lambda}=\frac{2.998\times10^8\ \text{m/s}}{4.341\times10^{-7}\ \text{m}}=6.906\times10^{14}\ \text{Hz}$.

(c) $E=hf=(6.626\times10^{-34}\ \text{J}\cdot\text{s})(6.906\times10^{14}\ \text{Hz})=4.576\times10^{-19}\ \text{J}=2.856\ \text{eV}$.

EVALUATE: Section 39.3 shows that the longest wavelength in the Balmer series (H_α) is 656 nm and the shortest is 365 nm. Our result for H_γ falls within this range. The photon energies for hydrogen atom transitions are in the eV range, and our result is of this order.

39.31. IDENTIFY: We know the power of the laser beam, so we know the energy per second that it delivers. The wavelength of the light tells us the energy of each photon, so we can use that to calculate the number of photons delivered per second.

SET UP: The energy of each photon is $E=hf=\frac{hc}{\lambda}=\frac{1.99\times10^{-25}\ \text{J}\cdot\text{m}}{\lambda}$. The power is the total energy per second and the total energy E_{tot} is the number of photons N times the energy E of each photon.

EXECUTE: $\lambda=10.6\times10^{-6}\ \text{m}$, so $E=1.88\times10^{-20}\ \text{J}$. $P=\frac{E_{\text{tot}}}{t}=\frac{NE}{t}$ so

$$\frac{N}{t}=\frac{P}{E}=\frac{0.100\times10^3\ \text{W}}{1.88\times10^{-20}\ \text{J}}=5.32\times10^{21}\ \text{photons/s}.$$

EVALUATE: At over 10^{21} photons per second, we can see why we do not detect individual photons.

39.32. IDENTIFY: We can calculate the energy of a photon from its wavelength. Knowing the intensity of the beam and the energy of a single photon, we can determine how many photons strike the blemish with each pulse.

SET UP: The energy of each photon is $E = hf = \dfrac{hc}{\lambda} = \dfrac{1.99\times10^{-25}\ \text{J}\cdot\text{m}}{\lambda}$. The power is the total energy per second and the total energy E_{tot} is the number of photons N times the energy E of each photon. The photon beam is spread over an area $A = \pi r^2$ with $r = 2.5$ mm.

EXECUTE: **(a)** $\lambda = 585$ nm and $E = \dfrac{hc}{\lambda} = 3.40\times10^{-19}\ \text{J} = 2.12\ \text{eV}$.

(b) $P = \dfrac{E_{\text{tot}}}{t} = \dfrac{NE}{t}$, so $N = \dfrac{Pt}{E} = \dfrac{(20.0\ \text{W})(0.45\times10^{-3}\ \text{s})}{3.40\times10^{-19}\ \text{J}} = 2.65\times10^{16}$ photons. These photons are spread over an area πr^2, so the number of photons per mm^2 is

$$\frac{2.65\times10^{16}\ \text{photons}}{\pi(2.5\ \text{mm})^2} = 1.35\times10^{15}\ \text{photons/mm}^2.$$

EVALUATE: With so many photons per mm^2, it is impossible to detect individual photons.

39.33. **IDENTIFY** and **SET UP:** The number of photons emitted each second is the total energy emitted divided by the energy of one photon. The energy of one photon is given by $E = hc/\lambda$. $E = Pt$ gives the energy emitted by the laser in time t.

EXECUTE: In 1.00 s the energy emitted by the laser is $(7.50\times10^{-3}\ \text{W})(1.00\ \text{s}) = 7.50\times10^{-3}$ J.

The energy of each photon is $E = \dfrac{hc}{\lambda} = \dfrac{(6.626\times10^{-34}\ \text{J}\cdot\text{s})(2.998\times10^{8}\ \text{m/s})}{10.6\times10^{-6}\ \text{m}} = 1.874\times10^{-20}$ J.

Therefore $\dfrac{7.50\times10^{-3}\ \text{J/s}}{1.874\times10^{-20}\ \text{J/photon}} = 4.00\times10^{17}$ photons/s.

EVALUATE: The number of photons emitted per second is extremely large.

39.34. **IDENTIFY** and **SET UP:** Visible light has wavelengths from about 380 nm to about 750 nm. The energy of each photon is $E = hf = \dfrac{hc}{\lambda} = \dfrac{1.99\times10^{-25}\ \text{J}\cdot\text{m}}{\lambda}$. The power is the total energy per second and the total energy E_{tot} is the number of photons N times the energy E of each photon.

EXECUTE: **(a)** 193 nm is shorter than the shortest wavelength of visible light so is in the ultraviolet.

(b) $E = \dfrac{hc}{\lambda} = 1.03\times10^{-18}\ \text{J} = 6.44\ \text{eV}$.

(c) $P = \dfrac{E_{\text{tot}}}{t} = \dfrac{NE}{t}$, so $N = \dfrac{Pt}{E} = \dfrac{(1.50\times10^{-3}\ \text{W})(12.0\times10^{-9}\ \text{s})}{1.03\times10^{-18}\ \text{J}} = 1.75\times10^{7}$ photons.

EVALUATE: A very small amount of energy is delivered to the lens in each pulse, but this still corresponds to a large number of photons.

39.35. **IDENTIFY:** Apply the equation $\dfrac{n_{\text{ex}}}{n_{\text{g}}} = e^{-(E_{\text{ex}}-E_{\text{g}})/kT}$ from the section on the laser.

SET UP: The energy of each of these excited states above the ground state is hc/λ, where λ is the wavelength of the photon emitted in the transition from the excited state to the ground state.

EXECUTE: $\dfrac{n_{2P_{3/2}}}{n_{2P_{1/2}}} = e^{-(E_{2P3/2} - E_{2P1/2})/KT}$. From the diagram

$$\Delta E_{3/2-\text{g}} = \frac{hc}{\lambda_1} = \frac{(6.626\times10^{-34}\ \text{J})(2.998\times10^{8}\,\text{m/s})}{5.890\times10^{-7}\ \text{m}} = 3.373\times10^{-19}\ \text{J}.$$

$$\Delta E_{1/2-\text{g}} = \frac{hc}{\lambda_2} = \frac{(6.626\times10^{-34}\ \text{J})(2.998\times10^{8}\ \text{m/s})}{5.896\times10^{-7}\ \text{m}} = 3.369\times10^{-19}\ \text{J}.$$

So $\Delta E_{3/2-1/2} = 3.373\times10^{-19}\text{ J} - 3.369\times10^{-19}\text{ J} = 4.00\times10^{-22}\text{ J}.$

$\dfrac{n_{2P_{3/2}}}{n_{2P_{1/2}}} = e^{-(4.00\times10^{-22}\text{ J})/(1.38\times10^{-23}\text{J/K}\cdot 500\text{ K})} = 0.944.$ So more atoms are in the $2P_{1/2}$ state.

EVALUATE: At this temperature $kT = 6.9\times10^{-21}$ J. This is greater than the energy separation between the states, so an atom has almost equal probability for being in either state, with only a small preference for the lower energy state.

39.36. **IDENTIFY:** This problem involves blackbody radiation and the Wien law.

SET UP and **EXECUTE:** $I = \sigma T^4$, Wien law: $\lambda_m = \dfrac{2.90\times10^{-3}\text{ m}\cdot\text{K}}{T}$. We want the change in the peak wavelength if the intensity I increases by a factor of 16. From $I = \sigma T^4$ we see that if I changes by a factor of 16, so does T^4. Thus T increases by a factor of 2 because $2^4 = 16$. From the Wien law, if T increases by a factor of 2, the peak wavelength decreases by a factor of $\frac{1}{2}$, so it is *halved*.

EVALUATE: All the temperatures must be in kelvin units.

39.37. **IDENTIFY:** Energy radiates at the rate $H = Ae\sigma T^4$.

SET UP: The surface area of a cylinder of radius r and length l is $A = 2\pi rl$.

EXECUTE: **(a)** $T = \left(\dfrac{H}{Ae\sigma}\right)^{1/4} = \left(\dfrac{100\text{ W}}{2\pi(0.20\times10^{-3}\text{ m})(0.30\text{ m})(0.26)(5.671\times10^{-8}\text{ W/m}^2\cdot\text{K}^4)}\right)^{1/4}.$

$T = 2.06\times10^3$ K.

(b) $\lambda_m T = 2.90\times10^{-3}\text{ m}\cdot\text{K};\ \lambda_m = 1410\text{ nm}.$

EVALUATE: **(c)** λ_m is in the infrared. The incandescent bulb is not a very efficient source of visible light because much of the emitted radiation is in the infrared.

39.38. **IDENTIFY:** Apply Wien's displacement law and $c = f\lambda$.

SET UP: T in kelvins gives λ in meters.

EXECUTE: **(a)** $\lambda_m = \dfrac{2.90\times10^{-3}\text{ m}\cdot\text{K}}{3.00\text{ K}} = 0.966\text{ mm}$, and $f = \dfrac{c}{\lambda_m} = 3.10\times10^{11}$ Hz.

(b) A factor of 100 increase in the temperature lowers λ_m by a factor of 100 to 9.66 μm and raises the frequency by the same factor, to 3.10×10^{13} Hz.

(c) Similarly, $\lambda_m = 966$ nm and $f = 3.10\times10^{14}$ Hz.

EVALUATE: λ_m decreases when T increases, as explained in the textbook.

39.39. **IDENTIFY** and **SET UP:** The wavelength λ_m where the Planck distribution peaks is given by Wien's displacement law, $\lambda_m T = 2.90\times10^{-3}\text{ m}\cdot\text{K}$.

EXECUTE: $\lambda_m = \dfrac{2.90\times10^{-3}\text{ m}\cdot\text{K}}{2.728\text{ K}} = 1.06\times10^{-3}\text{ m} = 1.06\text{ mm}.$

EVALUATE: This wavelength is in the microwave portion of the electromagnetic spectrum. This radiation is often referred to as the "microwave background" (Chapter 44). Note that in Wien's law, T must be in kelvins.

39.40. **IDENTIFY:** Apply Wien's displacement law.

SET UP: $\lambda_m T = 2.90\times10^{-3}\text{ m}\cdot\text{K}$.

EXECUTE: <u>For 10.0-μm infrared</u>: $T = \dfrac{2.90\times10^{-3}\text{ m}\cdot\text{K}}{\lambda_m} = \dfrac{2.90\times10^{-3}\text{ m}\cdot\text{K}}{10.0\times10^{-6}\text{ m}} = 290\text{ K}.$

For 600-nm visible: $T = \dfrac{2.90\times10^{-3}\ \text{m}\cdot\text{K}}{\lambda_\text{m}} = \dfrac{2.90\times10^{-3}\ \text{m}\cdot\text{K}}{600\times10^{-9}\ \text{m}} = 4830\ \text{K}.$

For 100-nm ultraviolet: $T = \dfrac{2.90\times10^{-3}\ \text{m}\cdot\text{K}}{\lambda_\text{m}} = \dfrac{2.90\times10^{-3}\ \text{m}\cdot\text{K}}{100\times10^{-9}\ \text{m}} = 29{,}000\ \text{K}.$

EVALUATE: Most materials would melt (or burn or vaporize) before reaching 29,000 K!

39.41. **IDENTIFY:** Since the stars radiate as blackbodies, they obey the Stefan-Boltzmann law and Wien's displacement law.

SET UP: The Stefan-Boltzmann law says that the intensity of the radiation is $I = \sigma T^4$, so the total radiated power is $P = \sigma A T^4$. Wien's displacement law tells us that the peak-intensity wavelength is $\lambda_\text{m} = (\text{constant})/T$.

EXECUTE: **(a)** The hot and cool stars radiate the same total power, so the Stefan-Boltzmann law gives $\sigma A_\text{h} T_\text{h}^4 = \sigma A_\text{c} T_\text{c}^4 \Rightarrow 4\pi R_\text{h}^2 T_\text{h}^4 = 4\pi R_\text{c}^2 T_\text{c}^4 = 4\pi (3R_\text{h})^2 T_\text{c}^4 \Rightarrow T_\text{h}^4 = 9T^4 \Rightarrow T_\text{h} = T\sqrt{3} = 1.7T$, rounded to two significant digits.

(b) Using Wien's law, we take the ratio of the wavelengths, giving $\dfrac{\lambda_\text{m}(\text{hot})}{\lambda_\text{m}(\text{cool})} = \dfrac{T_\text{c}}{T_\text{h}} = \dfrac{T}{T\sqrt{3}} = \dfrac{1}{\sqrt{3}} = 0.58,$ rounded to two significant digits.

EVALUATE: Although the hot star has only 1/9 the surface area of the cool star, its absolute temperature has to be only 1.7 times as great to radiate the same amount of energy.

39.42. **IDENTIFY:** Since the stars radiate as blackbodies, they obey the Stefan-Boltzmann law.

SET UP: The Stefan-Boltzmann law says that the intensity of the radiation is $I = \sigma T^4$, so the total radiated power is $P = \sigma A T^4$.

EXECUTE: **(a)** $I = \sigma T^4 = (5.67\times10^{-8}\ \text{W/m}^2\cdot\text{K}^4)(24{,}000\ \text{K})^4 = 1.9\times10^{10}\ \text{W/m}^2.$

(b) Wien's law gives $\lambda_\text{m} = (0.00290\ \text{m}\cdot\text{K})/(24{,}000\ \text{K}) = 1.2\times10^{-7}\,\text{m} = 20\ \text{nm}.$

This is not visible since the wavelength is less than 400 nm.

(c) $P = AI \Rightarrow 4\pi R^2 = P/I = (1.00\times10^{25}\ \text{W})/(1.9\times10^{10}\ \text{W/m}^2)$, which gives

$$R_\text{Sirius} = 6.51\times10^6\ \text{m} = 6510\ \text{km}.$$

$R_\text{Sirius}/R_\text{sun} = (6.51\times10^6\ \text{m})/(6.96\times10^9\ \text{m}) = 0.0093$, which gives

$$R_\text{Sirius} = 0.0093\ R_\text{sun} \approx 1\%\ R_\text{sun}.$$

(d) Using the Stefan-Boltzmann law, we have

$$\frac{P_\text{sun}}{P_\text{Sirius}} = \frac{\sigma A_\text{sun} T_\text{sun}^4}{\sigma A_\text{Sirius} T_\text{Sirius}^4} = \frac{4\pi R_\text{sun}^2 T_\text{sun}^4}{4\pi R_\text{Sirius}^2 T_\text{Sirius}^4}$$

$$= \left(\frac{R_\text{sun}}{R_\text{Sirius}}\right)^2 \left(\frac{T_\text{sun}}{T_\text{Sirius}}\right)^4 \cdot \frac{P_\text{sun}}{P_\text{Sirius}} = \left(\frac{R_\text{sun}}{0.00935 R_\text{sun}}\right)^2 \left(\frac{5800\ \text{K}}{24{,}000\ \text{K}}\right)^4 = 39.$$

EVALUATE: Even though the absolute surface temperature of Sirius B is about 4 times that of our sun, it radiates only 1/39 times as much energy per second as our sun because it is so small.

39.43. **IDENTIFY:** Apply the Heisenberg uncertainty principle.

SET UP: $\Delta p_x = m\Delta v_x$.

EXECUTE: **(a)** $(\Delta x)(m\Delta v_x) \ge \hbar/2$, and setting $\Delta v_x = (0.010)v_x$ and the product of the uncertainties equal to $\hbar/2$ (for the minimum uncertainty) gives $v_x = \dfrac{\hbar}{2m(0.010)\Delta x}$

$= \dfrac{1.055\times10^{-34}\ \text{J}\cdot\text{s}}{2(9.109\times10^{-31}\ \text{kg})(0.010)(0.30\times10^{-4}\ \text{m})} = 19.3\ \text{m/s},$ which rounds to 19 m/s.

(b) Taking the ratio of the equation for the proton to the equation for the electron gives

$$v_{\rm p} = \frac{m_{\rm e}}{m_{\rm p}}v_{\rm e} = \frac{9.109\times10^{-31}\ \text{kg}}{1.673\times10^{-27}\ \text{kg}}\cdot(19.3\ \text{m/s}) = 10.5\ \text{mm/s, which rounds to 11 mm/s.}$$

EVALUATE: For a given Δp_x, Δv_x is smaller for a proton than for an electron, since the proton has larger mass.

39.44. **IDENTIFY:** Since we know only that the mosquito is somewhere in the room, there is an uncertainty in its position. The Heisenberg uncertainty principle tells us that there is an uncertainty in its momentum.
SET UP: The uncertainty principle is $\Delta x\Delta p_x \ge \hbar/2$.

EXECUTE: **(a)** You know the mosquito is somewhere in the room, so the maximum uncertainty in its horizontal position is $\Delta x = 5.0$ m.

(b) The uncertainty principle gives $\Delta x\Delta p_x \ge \hbar/2$, and $\Delta p_x = m\Delta v_x$ since we know the mosquito's mass. This gives $\Delta x\, m\Delta v_x \ge \hbar/2$, which we can solve for Δv_x to get the minimum uncertainty in v_x.

$$\Delta v_x = \frac{\hbar}{2m\Delta x} = \frac{1.055\times10^{-34}\ \text{J}\cdot\text{s}}{2(1.5\times10^{-6}\ \text{kg})(5.0\ \text{m})} = 7.0\times10^{-30}\ \text{m/s, which is hardly a serious impediment!}$$

EVALUATE: For something as "large" as a mosquito, the uncertainty principle places a negligible limitation on our ability to measure its speed.

39.45. **IDENTIFY** and **SET UP:** The Heisenberg Uncertainty Principle says $\Delta x\Delta p_x \ge \hbar/2$. The minimum allowed $\Delta x\Delta p_x$ is $\hbar/2$. $\Delta p_x = m\Delta v_x$.

EXECUTE: **(a)** $m\Delta x\Delta v_x = \hbar/2$. $\Delta v_x = \dfrac{\hbar}{2m\Delta x} = \dfrac{1.055\times10^{-34}\ \text{J}\cdot\text{s}}{2(1.67\times10^{-27}\ \text{kg})(2.0\times10^{-12}\ \text{m})} = 1.6\times10^4\ \text{m/s}.$

(b) $\Delta x = \dfrac{\hbar}{2m\Delta v_x} = \dfrac{1.055\times10^{-34}\ \text{J}\cdot\text{s}}{2(9.11\times10^{-31}\ \text{kg})(0.250\ \text{m/s})} = 2.3\times10^{-4}\ \text{m}.$

EVALUATE: The smaller Δx is, the larger Δv_x must be.

39.46. **IDENTIFY:** Since we know that the marble is somewhere on the table, there is an uncertainty in its position. The Heisenberg uncertainty principle tells us that there is therefore an uncertainty in its momentum.
SET UP: The uncertainty principle is $\Delta x\Delta p_x \ge \hbar/2$.

EXECUTE: **(a)** Since the marble is somewhere on the table, the maximum uncertainty in its horizontal position is $\Delta x = 1.75$ m.

(b) Following the same procedure as in part (b) of Problem 39.44, the minimum uncertainty in the horizontal velocity of the marble is $\Delta v_x = \dfrac{\hbar}{2m\Delta x} = \dfrac{1.055\times10^{-34}\ \text{J}\cdot\text{s}}{2(0.0100\ \text{kg})(1.75\ \text{m})} = 3.01\times10^{-33}\ \text{m/s}.$

(c) The uncertainty principle tells us that we cannot know that the marble's horizontal velocity is *exactly* zero, so the smallest we could measure it to be is 3.01×10^{-33} m/s, from part (b). The longest time it could remain on the table is the time to travel the full width of the table (1.75 m), so $t = x/v_x$ $= (1.75\ \text{m})/(3.01\times10^{-33}\ \text{m/s}) = 5.81\times10^{32}\ \text{s} = 1.84\times10^{25}$ years. Since the universe is about 14×10^9 years old, this time is about $\dfrac{1.8\times10^{25}\ \text{yr}}{14\times10^9\ \text{yr}} \approx 1.3\times10^{15}$ times the age of the universe! Don't hold your breath!
EVALUATE: For household objects, the uncertainty principle places a negligible limitation on our ability to measure their speed.

39.47. **IDENTIFY:** The Heisenberg uncertainty principle tells us that $\Delta x \Delta p_x \geq \hbar/2$.

SET UP: We can treat the standard deviation as a direct measure of uncertainty.

EXECUTE: Here $\Delta x \Delta p_x = (1.2\times10^{-10}\ \text{m})(3.0\times10^{-25}\ \text{kg}\cdot\text{m/s}) = 3.6\times10^{-35}\ \text{J}\cdot\text{s}$, but $\hbar/2 = 5.28\times10^{-35}\ \text{J}\cdot\text{s}$. Therefore $\Delta x \Delta p_x < \hbar/2$, so the claim is *not valid*.

EVALUATE: The uncertainty product $\Delta x \Delta p_x$ must increase by a factor of about 1.5 to become consistent with the Heisenberg uncertainty principle.

39.48. **IDENTIFY:** Apply conservation of momentum to the system of atom and emitted photon.

SET UP: Assume the atom is initially at rest. For a photon $E = \dfrac{hc}{\lambda}$ and $p = \dfrac{h}{\lambda}$.

EXECUTE: **(a)** Assume a non-relativistic velocity and conserve momentum $\Rightarrow mv = \dfrac{h}{\lambda} \Rightarrow v = \dfrac{h}{m\lambda}$.

(b) $K = \dfrac{1}{2}mv^2 = \dfrac{1}{2}m\left(\dfrac{h}{m\lambda}\right)^2 = \dfrac{h^2}{2m\lambda^2}$.

(c) $\dfrac{K}{E} = \dfrac{h^2}{2m\lambda^2}\cdot\dfrac{\lambda}{hc} = \dfrac{h}{2mc\lambda}$. Recoil becomes an important concern for small m and small λ since this ratio becomes large in those limits.

(d) $E = 10.2\ \text{eV} \Rightarrow \lambda = \dfrac{hc}{E} = \dfrac{(6.63\times10^{-34}\ \text{J}\cdot\text{s})(3.00\times10^{8}\ \text{m/s})}{(10.2\ \text{eV})(1.60\times10^{-19}\ \text{J/eV})} = 1.22\times10^{-7}\ \text{m} = 122\ \text{nm}.$

$$K = \frac{(6.63\times10^{-34}\ \text{J}\cdot\text{s})^2}{2(1.67\times10^{-27}\ \text{kg})(1.22\times10^{-7}\ \text{m})^2} = 8.84\times10^{-27}\ \text{J} = 5.53\times10^{-8}\ \text{eV}.$$

$\dfrac{K}{E} = \dfrac{5.53\times10^{-8}\ \text{eV}}{10.2\ \text{eV}} = 5.42\times10^{-9}$. This is quite small so recoil can be neglected.

EVALUATE: For emission of photons with ultraviolet or longer wavelengths the recoil kinetic energy of the atom is much less than the energy of the emitted photon.

39.49. **(a) IDENTIFY** and **SET UP:** Apply the equation for the reduced mass, $m_\text{r} = \dfrac{m_1 m_2}{m_1 + m_2} = \dfrac{207 m_\text{e} m_\text{p}}{207 m_\text{e} + m_\text{p}}$, where m_e denotes the electron mass.

EXECUTE: $m_\text{r} = \dfrac{207(9.109\times10^{-31}\ \text{kg})(1.673\times10^{-27}\ \text{kg})}{207(9.109\times10^{-31}\ \text{kg}) + 1.673\times10^{-27}\ \text{kg}} = 1.69\times10^{-28}\ \text{kg}.$

(b) IDENTIFY: In the energy equation $E_n = -\dfrac{1}{\epsilon_0^2}\dfrac{me^4}{8n^2h^2}$, replace $m = m_\text{e}$ by m_r: $E_n = -\dfrac{1}{\epsilon_0^2}\dfrac{m_\text{r}e^4}{8n^2h^2}$.

SET UP: Write as $E_n = \left(\dfrac{m_\text{r}}{m_\text{H}}\right)\left(-\dfrac{1}{\epsilon_0^2}\dfrac{m_\text{H}e^4}{8n^2h^2}\right)$, since we know that $\dfrac{1}{\epsilon_0^2}\dfrac{m_\text{H}e^4}{8h^2} = 13.60\ \text{eV}$. Here m_H denotes the reduced mass for the hydrogen atom; $m_\text{H} = (0.99946)(9.109\times10^{-31}\ \text{kg}) = 9.104\times10^{-31}\ \text{kg}$.

EXECUTE: $E_n = \left(\dfrac{m_\text{r}}{m_\text{H}}\right)\left(-\dfrac{13.60\ \text{eV}}{n^2}\right)$.

$$E_1 = \frac{1.69\times10^{-28}\ \text{kg}}{9.104\times10^{-31}\ \text{kg}}(-13.60\ \text{eV}) = 186(-13.60\ \text{eV}) = -2.53\ \text{keV}.$$

(c) SET UP: From part (b), $E_n = \left(\frac{m_r}{m_H}\right)\left(-\frac{R_H ch}{n^2}\right)$, where $R_H = 1.097\times10^7\ \text{m}^{-1}$ is the Rydberg constant for the hydrogen atom. Use this result in $\frac{hc}{\lambda} = E_i - E_f$ to find an expression for $1/\lambda$. The initial level for the transition is the $n_i = 2$ level and the final level is the $n_f = 1$ level.

EXECUTE: $\frac{hc}{\lambda} = \frac{m_r}{m_H}\left[-\frac{R_H ch}{n_i^2} - \left(-\frac{R_H ch}{n_f^2}\right)\right]$.

$$\frac{1}{\lambda} = \frac{m_r}{m_H} R_H \left(\frac{1}{n_f^2} - \frac{1}{n_i^2}\right).$$

$$\frac{1}{\lambda} = \frac{1.69\times10^{-28}\ \text{kg}}{9.104\times10^{-31}\ \text{kg}}(1.097\times10^7\ \text{m}^{-1})\left(\frac{1}{1^2} - \frac{1}{2^2}\right) = 1.527\times10^9\ \text{m}^{-1}.$$

$\lambda = 0.655$ nm.

EVALUATE: From Example 39.6, the wavelength of the radiation emitted in this transition in hydrogen is 122 nm. The wavelength for muonium is $\frac{m_H}{m_r} = 5.39\times10^{-3}$ times this. The reduced mass for hydrogen is very close to the electron mass because the electron mass is much less then the proton mass: $m_p/m_e = 1836$. The muon mass is $207m_e = 1.886\times10^{-28}$ kg. The proton is only about 10 times more massive than the muon, so the reduced mass is somewhat smaller than the muon mass. The muon–proton atom has much more strongly bound energy levels and much shorter wavelengths in its spectrum than for hydrogen.

39.50. IDENTIFY: This problem involves the energy levels in the Bohr atom.

SET UP: $E_n = -(13.60\ \text{eV})/n^2$, $E = hc/\lambda$. We want the wavelength.

EXECUTE: The energy of the photon is the sum of the energy to ionize the atom plus the kinetic energy of the electron. So $hc/\lambda = (13.60\ \text{eV})/n^2 + K$. Using $n = 3$ and $K = 8.00$ eV and solving for the wavelength gives $\lambda = 130$ nm.

EVALUATE: This light is not visible to humans.

39.51. IDENTIFY: This problem involves the Pickering emission series and the Bohr atom.

SET UP: $\frac{1}{\lambda} = (1.097\times10^7\ \text{m}^{-1})\left[\frac{1}{4} - \frac{1}{(n/2)^2}\right]$, $n = 5, 6, \ldots$

EXECUTE: (a) We want the longest and shortest wavelengths of the Pickering series. For the longest wavelength (the least energy), the transition is between adjacent levels, so $n = 5$.

$$\frac{1}{\lambda} = (1.097\times10^7\ \text{m}^{-1})\left[\frac{1}{4} - \frac{1}{(5/2)^2}\right].\ \lambda = 1013\ \text{nm}.$$

For shortest wavelength, n approaches infinity.

$$\frac{1}{\lambda} = (1.097\times10^7\ \text{m}^{-1})\left[\frac{1}{4} - \frac{1}{(\infty/2)^2}\right].\ \lambda = 364.6\ \text{nm}.$$

(b) Shortest wavelength: The transition is between n_L and infinity. The Bohr energy is $\Delta E = E_\infty - E_{n_L}$.

$\frac{hc}{\lambda_{min}} = \frac{Z^2 E_1}{n^2}$. $E_1 = 13.60$ eV and $\lambda_{min} = 364.6$ nm which gives $Z^2/n^2 = 0.250$. Try values of n to find a Z that satisfies this equation.

$n = 1$: This cannot work because Z must be a whole number.

$n = 2$: This gives $Z = 1$, which is hydrogen which we know is *not* the atom.

n = 3: Z is not a whole number.
n = 4: This gives Z = 2 and ends on level 4, so n_L = 4, Z = 2 (helium).
EVALUATE: Find n for the $\lambda = 1013$ nm transition using the Bohr model for a Z = 2 atom.

$$\Delta E = \frac{hc}{\lambda} = Z^2(13.60\text{ eV})\left(\frac{1}{4^2} - \frac{1}{n^2}\right).$$

Using $\lambda = 1013$ nm and Z = 2 gives n = 5, so the transition is from the n = 5 state to the n = 4 state.

39.52. **IDENTIFY** and **SET UP:** The de Broglie wavelength is $\lambda = \dfrac{h}{p} = \dfrac{h}{mv}$. In the Bohr model, $mvr_n = n(h/2\pi)$, so $mv = nh/(2\pi r_n)$. Combine these two expressions and obtain an equation for λ in terms of n. Then $\lambda = h\left(\dfrac{2\pi r_n}{nh}\right) = \dfrac{2\pi r_n}{n}$.

EXECUTE: **(a)** For $n = 1, \lambda = 2\pi r_1$ with $r_1 = a_0 = 0.529 \times 10^{-10}$ m, so
$\lambda = 2\pi(0.529 \times 10^{-10}\text{ m}) = 3.32 \times 10^{-10}$ m.
$\lambda = 2\pi r_1$; the de Broglie wavelength equals the circumference of the orbit.
(b) For $n = 4, \lambda = 2\pi r_4/4$.

$$r_n = n^2 a_0 \text{ so } r_4 = 16a_0.$$
$$\lambda = 2\pi(16a_0)/4 = 4(2\pi a_0) = 4(3.32 \times 10^{-10}\text{ m}) = 1.33 \times 10^{-9}\text{ m}.$$

$\lambda = 2\pi r_4/4$; the de Broglie wavelength is $\dfrac{1}{n} = \dfrac{1}{4}$ times the circumference of the orbit.

EVALUATE: As n increases the momentum of the electron increases and its de Broglie wavelength decreases. For any n, the circumference of the orbits equals an integer number of de Broglie wavelengths.

39.53. **(a) IDENTIFY** and **SET UP:** The photon energy is given to the electron in the atom. Some of this energy overcomes the binding energy of the atom and what is left appears as kinetic energy of the free electron. Apply $hf = E_f - E_i$, the energy given to the electron in the atom when a photon is absorbed.

EXECUTE: The energy of one photon is $\dfrac{hc}{\lambda} = \dfrac{(6.626 \times 10^{-34}\text{ J}\cdot\text{s})(2.998 \times 10^8\text{ m/s})}{85.5 \times 10^{-9}\text{ m}}$.

$$\frac{hc}{\lambda} = 2.323 \times 10^{-18}\text{ J}(1\text{ eV}/1.602 \times 10^{-19}\text{ J}) = 14.50\text{ eV}.$$

The final energy of the electron is $E_f = E_i + hf$. In the ground state of the hydrogen atom the energy of the electron is $E_i = -13.60$ eV. Thus $E_f = -13.60\text{ eV} + 14.50\text{ eV} = 0.90$ eV.

EVALUATE: **(b)** At thermal equilibrium a few atoms will be in the $n = 2$ excited levels, which have an energy of $-13.6\text{ eV}/4 = -3.40\text{ eV}, 10.2\text{ eV}$ greater than the energy of the ground state. If an electron with $E = -3.40$ eV gains 14.5 eV from the absorbed photon, it will end up with $14.5\text{ eV} - 3.4\text{ eV} = 11.1\text{ eV}$ of kinetic energy.

39.54. **IDENTIFY:** We are dealing with transitions between states having very close energies.
SET UP: E_n is the energy of state n relative to ground, so the photon energies due to the transitions are $E_1 = hc/\lambda_1$ and $E_2 = hc/\lambda_2$.
EXECUTE: (a)

$$\Delta E = |E_1 - E_2| = hc\left|\frac{1}{\lambda_1} - \frac{1}{\lambda_2}\right| = hc\left|\frac{\lambda_2 - \lambda_1}{\lambda_1 \lambda_2}\right| \approx \frac{hc\Delta\lambda}{\lambda^2}$$

(b) Using the given numbers gives

$$\Delta E \approx \frac{hc(589.6\ \text{nm} - 589.0\ \text{nm})}{(589.6\ \text{nm})^2} = 0.002\ \text{eV}.$$

EVALUATE: Using 589.0 nm in the denominator in part (b) would give the same answer.

39.55. **IDENTIFY:** Assuming that Betelgeuse radiates like a perfect blackbody, Wien's displacement and the Stefan-Boltzmann law apply to its radiation.

SET UP: Wien's displacement law is $\lambda_{\text{peak}} = \dfrac{2.90\times 10^{-3}\ \text{m}\cdot\text{K}}{T}$, and the Stefan-Boltzmann law says that the intensity of the radiation is $I = \sigma T^4$, so the total radiated power is $P = \sigma A T^4$.

EXECUTE: **(a)** First use Wien's law to find the peak wavelength:

$$\lambda_{\text{m}} = (2.90\times 10^{-3}\ \text{m}\cdot\text{K})/(3000\ \text{K}) = 9.667\times 10^{-7}\ \text{m}.$$

Call N the number of photons/second radiated. $N \times (\text{energy per photon}) = IA = \sigma A T^4$.

$$N(hc/\lambda_{\text{m}}) = \sigma A T^4.\quad N = \frac{\lambda_{\text{m}} \sigma A T^4}{hc}.$$

$$N = \frac{(9.667\times 10^{-7}\ \text{m})(5.67\times 10^{-8}\ \text{W/m}^2\cdot\text{K}^4)(4\pi)(600\times 6.96\times 10^8\ \text{m})^2(3000\ \text{K})^4}{(6.626\times 10^{-34}\ \text{J}\cdot\text{s})(3.00\times 10^8\ \text{m/s})}.$$

$$N = 5\times 10^{49}\ \text{photons/s}.$$

(b) $\dfrac{I_{\text{B}}A_{\text{B}}}{I_{\text{S}}A_{\text{S}}} = \dfrac{\sigma A_{\text{B}} T_{\text{B}}^4}{\sigma A_{\text{S}} T_{\text{S}}^4} = \dfrac{4\pi R_{\text{B}}^2 T_{\text{B}}^4}{4\pi R_{\text{S}}^2 T_{\text{S}}^4} = \left(\dfrac{600 R_{\text{S}}}{R_{\text{S}}}\right)^2 \left(\dfrac{3000\ \text{K}}{5800\ \text{K}}\right)^4 = 3\times 10^4.$

EVALUATE: Betelgeuse radiates 30,000 times as much energy per second as does our sun!

39.56. **IDENTIFY:** The diffraction grating allows us to determine the peak-intensity wavelength of the light. Then Wien's displacement law allows us to calculate the temperature of the blackbody, and the Stefan-Boltzmann law allows us to calculate the rate at which it radiates energy.

SET UP: The bright spots for a diffraction grating occur when $d\sin\theta = m\lambda$. Wien's displacement law is $\lambda_{\text{peak}} = \dfrac{2.90\times 10^{-3}\ \text{m}\cdot\text{K}}{T}$, and the Stefan-Boltzmann law says that the intensity of the radiation is $I = \sigma T^4$, so the total radiated power is $P = \sigma A T^4$. The area of a sphere is $A = 4\pi r^2$.

EXECUTE: **(a)** First find the wavelength of the light:

$$\lambda = d\sin\theta = [1/(385{,}000\ \text{lines/m})]\sin(14.4^\circ) = 6.459\times 10^{-7}\ \text{m}.$$

Now use Wien's law to find the temperature: $T = (2.90\times 10^{-3}\ \text{m}\cdot\text{K})/(6.459\times 10^{-7}\ \text{m}) = 4490\ \text{K}$.

(b) The energy radiated by the blackbody is equal to the power times the time, giving $U = Pt = IAt = \sigma A T^4 t$, which gives

$t = U/(\sigma A T^4) = (12.0\times 10^6\ \text{J})/[(5.67\times 10^{-8}\ \text{W/m}^2\cdot\text{K}^4)(4\pi)(0.0750\ \text{m})^2(4490\ \text{K})^4] = 7.37\ \text{s}.$

EVALUATE: By ordinary standards, this blackbody is very hot, so it does not take long to radiate 12.0 MJ of energy.

39.57. **IDENTIFY:** We are applying quantum principles to our moon.

SET UP and **EXECUTE:** **(a)** We want the de Broglie wavelength of the moon. First find the speed. $v = 2\pi r/t$. Using the orbital radius r from Appendix F and $t = 27.3$ d = (27.3)(86,400 s), we have $v = 1.0229$ km/s. Now use $\lambda = h/p = h/mv$ with the mass m given in the problem and the speed we just found, giving $\lambda = 8.81 \times 10^{-60}$ m.

(b) We want the acceleration of the moon. Apply Newton's second law and universal gravitation to the moon. We also know that the angular momentum is $L = M_{\text{moon}}vR = mh/2\pi$, so $v = mh/2\pi M_{\text{moon}}R$. Using these relationships gives

$$\frac{GM_{\text{earth}}M_{\text{moon}}}{R^2} = \frac{M_{\text{moon}}v^2}{R}$$

$$\frac{GM_{\text{earth}}}{R} = v^2 = \left(\frac{mh}{2\pi M_{\text{moon}}R}\right)^2$$

$$R = m^2\left(\frac{h^2}{4\pi^2 M_{\text{moon}}^2 GM_{\text{earth}}}\right) = m^2\, a_{\text{moon}}$$

$$a_{\text{moon}} = \frac{h^2}{4\pi^2 M_{\text{moon}}^2 GM_{\text{earth}}}.$$

(c) We want a_{moon}. Using the numbers given in the problem for the masses, our result from part (b) gives $a_{\text{moon}} = 5.17 \times 10^{-129}\, m$ m/s^2.

(d) We want m. Using $R_{\text{m}} = m^2 a_{\text{moon}}$ and the result from part (c) gives $m = 2.73 \times 10^{68}$.

(e) We want E_0. From $E = -E_0/m$ we get $E_0 = -m^2E$. Using $E = K + U$ gives

$$E = \frac{1}{2}I\omega^2 - \frac{GM_{\text{moon}}M_{\text{earth}}}{R} = \frac{1}{2}M_{\text{moon}}R^2\left(\frac{2\pi}{T}\right)^2 - \frac{GM_{\text{moon}}M_{\text{earth}}}{R}.$$

Using $E_0 = -m^2E$ with the above result and $m = 2.73 \times 10^{68}$, we get $E_0 = -2.81 \times 10^{165}$ J.

EVALUATE: According to our result, the moon is not even close to its ground state.

39.58. **IDENTIFY:** Combine $I = \sigma T^4$, $P = IA$, and $\Delta E = Pt$.

SET UP: In the Stefan-Boltzmann law the temperature must be in kelvins. 400°C = 673 K.

EXECUTE: $t = \dfrac{\Delta E}{A\sigma T^4} = \dfrac{100\text{ J}}{(4.00\times10^{-6}\text{ m}^2)(5.67\times10^{-8}\text{ W/m}^2\cdot\text{K}^4)(673\text{ K})^4} = 2.15\times10^3\text{ s}$

$= 35.8\text{ min} = 0.597\text{ h}.$

EVALUATE: The power is $P = 46.5$ mW. Since the area of the hole is small, the rate at which the cavity radiates energy through the hole is very small.

39.59. **IDENTIFY** and **SET UP:** Follow the procedures specified in the problem.

EXECUTE: **(a)** $I(\lambda) = \dfrac{2\pi hc^2}{\lambda^5(e^{hc/\lambda kT}-1)}$ but $\lambda = \dfrac{c}{f} \Rightarrow I(f) = \dfrac{2\pi hc^2}{(c/f)^5(e^{hf/kT}-1)} = \dfrac{2\pi hf^5}{c^3(e^{hf/kT}-1)}.$

(b) $\displaystyle\int_0^\infty I(\lambda)\,d\lambda = \int_\infty^0 I(f)\,df\left(\frac{-c}{f^2}\right) = \int_0^\infty \frac{2\pi hf^3\,df}{c^2(e^{hf/kT}-1)} = \frac{2\pi(kT)^4}{c^2h^3}\int_0^\infty \frac{x^3}{e^x-1}\,dx = \frac{2\pi(kT)^4}{c^2h^3}\frac{1}{240}(2\pi)^4$

$= \dfrac{(2\pi)^5(kT)^4}{240h^3c^2} = \dfrac{2\pi^5k^4T^4}{15c^2h^3}.$

(c) The expression $\dfrac{2\pi^5k^4}{15h^3c^2} = \sigma$ as shown in Eq. (39.28). Plugging in the values for the constants we get $\sigma = 5.67\times10^{-8}\text{ W/m}^2\cdot\text{K}^4.$

EVALUATE: The Planck radiation law, $I(\lambda) = \dfrac{2\pi hc^2}{\lambda^5(e^{hc/\lambda kT}-1)}$, predicts the Stefan-Boltzmann law, $I = \sigma T^4$.

39.60. **IDENTIFY:** $\lambda = \frac{h}{p} = \frac{h}{\sqrt{2mE}}$. From Chapter 36, if $\lambda \ll a$ then the width w of the central maximum is $w = 2\frac{R\lambda}{a}$, where $R = 2.5\text{ m}$ and a is the width of the slit.

SET UP: $v_x = \sqrt{\frac{2E}{m}}$, since the beam is traveling in the x-direction and $\Delta v_y \ll v_x$.

EXECUTE: **(a)** $\lambda = \frac{h}{\sqrt{2mE}} = \frac{(6.63\times10^{-34}\text{ J}\cdot\text{s})}{\sqrt{2(9.11\times10^{-31}\text{ kg})(40\text{ eV})(1.60\times10^{-19}\text{ J/eV})}} = 1.94\times10^{-10}\text{ m}.$

(b) $\frac{R}{v} = \frac{R}{\sqrt{2E/m}} = \frac{(2.5\text{ m})(9.11\times10^{-31}\text{ kg})^{1/2}}{\sqrt{2(40\text{ eV})(1.6\times10^{-19}\text{ J/eV})}} = 6.67\times10^{-7}\text{ s}.$

(c) The width w is $w = 2R\frac{\lambda}{a}$' and $w = \Delta v_y t = \Delta p_y t/m$, where t is the time found in part (b) and a is the slit width. Combining the expressions for w, $\Delta p_y = \frac{2m\lambda R}{at} = 2.65\times10^{-28}\text{ kg}\cdot\text{m/s}.$

(d) $\Delta y = \frac{\hbar}{2\Delta p_y} = 0.20\ \mu\text{m}$, which is the same order of magnitude of the width of the slit.

EVALUATE: For these electrons $\lambda = 1.94\times10^{-10}\text{ m}$. This is much smaller than a and the approximate expression $w = \frac{2R\lambda}{a}$ is very accurate. Also, $v_x = \sqrt{\frac{2E}{m}} = 3.75\times10^6\text{ m/s}$. $\Delta v_y = \frac{\Delta p_y}{m} = 2.9\times10^2\text{ m/s}$, so it is the case that $v_x \gg \Delta v_y$.

39.61. **IDENTIFY:** This problem involves the de Broglie wavelength.
SET UP and **EXECUTE:** Use $\lambda = h/mv$. **(a)** Estimate: 0.5 mm/s.
(b) Using m = 85 kg gives $\lambda = h/mv = h/(85\text{ kg})(0.5\text{ mm/s}) = 1.6\times10^{-32}\text{ m}$.
(c) $\lambda = h/mv = h/(0.5\text{ mg})(0.5\text{ mm/s}) = 2.7\times10^{-24}\text{ m}$.
(d) $\lambda = h/mv = (1\text{ J·s})/(0.5\text{ mg})(1\text{ m/s}) = 2\times10^6\text{ m} = 2000\text{ km}$.
(e) $\lambda = h/mv = (1\text{ J·s})/(85\text{ kg})(2.5\text{ m/s}) = 4.7\text{ mm}$.
(f) We want the speed. Estimate: Doorway is 1.0 m wide. For single-slit diffraction, $\lambda = a\sin\theta = (1.0\text{ m})\sin 5° = 0.087\text{ m}$. $\lambda = h/mv = (1\text{ J·s})/[(0.145\text{ kg})(0.087\text{ m})] = 80\text{ m/s}$.
EVALUATE: From our results we can see that the wave nature of particles is not apparent for everyday-size things but only for particles of the scale of electrons, protons, atoms, and molecules.

39.62. **IDENTIFY:** The de Broglie wavelength of the electrons must be such that the first diffraction minimum occurs at $\theta = 20.0°$.

SET UP: The single-slit diffraction minima occur at angles θ given by $a\sin\theta = m\lambda$. $p = \frac{h}{\lambda}$.

EXECUTE: **(a)** $\lambda = a\sin\theta = (300\times10^{-9}\text{ m})(\sin 20°) = 1.0261\times10^{-7}\text{ m}$. $\lambda = h/mv \to v = h/m\lambda$.

$$v = \frac{6.626\times10^{-34}\text{ J}\cdot\text{s}}{(9.11\times10^{-31}\text{ kg})(1.0261\times10^{-7}\text{ m})} = 7.09\times10^3\text{ m/s} = 7.09\text{ km/s}.$$

(b) No electrons strike the screen at the location of the second diffraction minimum. $a\sin\theta_2 = 2\lambda$.

$$\sin\theta_2 = \pm2\frac{\lambda}{a} = \pm2\left(\frac{1.0261\times10^{-7}\text{ m}}{3.00\times10^{-7}\text{ m}}\right) = \pm0.684.\quad \theta_2 = \pm43.2°.$$

EVALUATE: The intensity distribution in the diffraction pattern depends on the wavelength λ and is the same for light of wavelength λ as for electrons with de Broglie wavelength λ.

39.63. IDENTIFY: The electrons behave like waves and produce a double-slit interference pattern after passing through the slits.

SET UP: The first angle at which destructive interference occurs is given by $d\sin\theta = \lambda/2$. The de Broglie wavelength of each of the electrons is $\lambda = h/mv$.

EXECUTE: **(a)** First find the wavelength of the electrons. For the first dark fringe, we have $d\sin\theta = \lambda/2$, which gives (1.25 nm)(sin 18.0°) = $\lambda/2$, and λ = 0.7725 nm. Now solve the de Broglie wavelength equation for the speed of the electron:

$$v = \frac{h}{m\lambda} = \frac{6.626\times10^{-34}\ \text{J}\cdot\text{s}}{(9.11\times10^{-31}\ \text{kg})(0.7725\times10^{-9}\ \text{m})} = 9.42\times10^{5}\ \text{m/s}$$

which is about 0.3% the speed of light, so they are *nonrelativistic*.

(b) Energy conservation gives $eV = \frac{1}{2}mv^2$ and $V = mv^2/2e$

$= (9.11\times10^{-31}\ \text{kg})(9.42\times10^{5}\ \text{m/s})^2/[2(1.60\times10^{-19}\ \text{C})] = 2.52\ \text{V}.$

EVALUATE: The de Broglie wavelength of the electrons is comparable to the separation of the slits.

30.64. IDENTIFY: The de Broglie wavelength of the electrons must equal the wavelength of the light.

SET UP: The maxima in the two-slit interference pattern are located by $d\sin\theta = m\lambda$. For an electron, $\lambda = \dfrac{h}{p} = \dfrac{h}{mv}$.

EXECUTE: $\lambda = \dfrac{d\sin\theta}{m} = \dfrac{(20.0\times10^{-6}\ \text{m})\sin(0.0300\ \text{rad})}{2} = 300\ \text{nm}.$ The velocity of an electron with this wavelength is given by $\lambda = h/p$. $v = \dfrac{p}{m} = \dfrac{h}{m\lambda} = \dfrac{(6.63\times10^{-34}\ \text{J}\cdot\text{s})}{(9.11\times10^{-31}\ \text{kg})(300\times10^{-9}\ \text{m})} = 2.43\times10^{3}\ \text{m/s}$ = 2.43 km/s.

Since this velocity is much smaller than c we can calculate the energy of the electron classically, so $K = \frac{1}{2}mv^2 = \frac{1}{2}(9.11\times10^{-31}\ \text{kg})(2.43\times10^{3}\ \text{m/s})^2 = 2.68\times10^{-24}\ \text{J} = 16.7\times10^{-6}\ \text{eV} = 16.7\ \mu\text{eV}$.

EVALUATE: The energy of the photons of this wavelength is $E = \dfrac{hc}{\lambda} = 4.14\ \text{eV}$. The photons and electrons have the same wavelength but a photon has around 250,000 times as much energy as an electron.

39.65. IDENTIFY: Both the electrons and photons behave like waves and exhibit single-slit diffraction after passing through their respective slits.

SET UP: The energy of the photon is $E = hc/\lambda$ and the de Broglie wavelength of the electron is $\lambda = h/mv = h/p$. Destructive interference for a single slit first occurs when $a\sin\theta = \lambda$.

EXECUTE: **(a)** For the photon: $\lambda = hc/E$ and $a\sin\theta = \lambda$. Since the a and θ are the same for the photons and electrons, they must both have the same wavelength. Equating these two expressions for λ gives $a\sin\theta = hc/E$. For the electron, $\lambda = h/p = \dfrac{h}{\sqrt{2mK}}$ and $a\ \Delta \to 0,$ Equating these two expressions for λ gives $a\sin\theta = \dfrac{h}{\sqrt{2mK}}$. Equating the two expressions for $a\sin\theta$ gives $hc/E = \dfrac{h}{\sqrt{2mK}}$, which gives $E = c\sqrt{2mK} = (4.05\times10^{-7}\ \text{J}^{1/2})\sqrt{K}$.

(b) $\dfrac{E}{K} = \dfrac{c\sqrt{2mK}}{K} = \sqrt{\dfrac{2mc^2}{K}}$. Since $v \ll c$, $mc^2 > K$, so the square root is > 1. Therefore $E/K > 1$, meaning that the photon has more energy than the electron.

EVALUATE: When a photon and a particle have the same wavelength, the photon has more energy than the particle.

39.66. IDENTIFY and SET UP: The de Broglie wavelength of the blood cell is $\lambda = \dfrac{h}{mv}$.

EXECUTE: $\lambda = \dfrac{6.63\times10^{-34}\ \text{J}\cdot\text{s}}{(1.00\times10^{-14}\ \text{kg})(4.00\times10^{-3}\ \text{m/s})} = 1.66\times10^{-17}\ \text{m}.$

EVALUATE: We need not be concerned about wave behavior.

39.67. IDENTIFY and SET UP: Follow the procedures specified in the problem.

EXECUTE: **(a)** $\lambda = \dfrac{h}{p} = \dfrac{h\left(1-\dfrac{v^2}{c^2}\right)^{1/2}}{mv} \Rightarrow \lambda^2 m^2 v^2 = h^2\left(1-\dfrac{v^2}{c^2}\right) = h^2 - \dfrac{h^2v^2}{c^2} \Rightarrow \lambda^2 m^2 v^2 + h^2\dfrac{v^2}{c^2} = h^2$

$\Rightarrow v^2 = \dfrac{h^2}{\left(\lambda^2 m^2 + \dfrac{h^2}{c^2}\right)} = \dfrac{c^2}{\left(\dfrac{\lambda^2 m^2 c^2}{h^2}+1\right)} \Rightarrow v = \dfrac{c}{\left(1+\left(\dfrac{mc\lambda}{h}\right)^2\right)^{1/2}}.$

(b) $v = \dfrac{c}{\left(1+\left(\dfrac{\lambda}{(h/mc)}\right)^2\right)^{1/2}} \approx c\left(1-\dfrac{1}{2}\left(\dfrac{mc\lambda}{h}\right)^2\right) = (1-\Delta)c.\ \ \Delta = \dfrac{m^2c^2\lambda^2}{2h^2}.$

(c) $\lambda = 1.00\times10^{-15}\,\text{m} \ll \dfrac{h}{mc}.\ \ \Delta = \dfrac{(9.11\times10^{-31}\ \text{kg})^2(3.00\times10^8\ \text{m/s})^2(1.00\times10^{-15}\ \text{m})^2}{2(6.63\times10^{-34}\ \text{J}\cdot\text{s})^2} = 8.50\times10^{-8}$

$\Rightarrow v = (1-\Delta)c = (1-8.50\times10^{-8})c.$

EVALUATE: As $\Delta \to 0,\ v \to c$ and $\lambda \to 0$.

39.68. IDENTIFY and SET UP: The minimum uncertainty product is $\Delta x \Delta p_x = \hbar/2$. $\Delta x = r_1$, where r_1 is the radius of the $n=1$ Bohr orbit. In the $n=1$ Bohr orbit, $mv_1r_1 = \dfrac{h}{2\pi}$ and $p_1 = mv_1 = \dfrac{h}{2\pi r_1}$.

EXECUTE: $\Delta p_x = \dfrac{\hbar}{2\Delta x} = \dfrac{\hbar}{2r_1} = \dfrac{1.055\times10^{-34}\ \text{J}\cdot\text{s}}{2(0.529\times10^{-10}\ \text{m})} = 1.0\times10^{-24}\ \text{kg}\cdot\text{m/s}.$ This is the same as the magnitude of the momentum of the electron in the $n=1$ Bohr orbit.

EVALUATE: Since the momentum is the same order of magnitude as the uncertainty in the momentum, the uncertainty principle plays a large role in the structure of atoms.

39.69. IDENTIFY and SET UP: Combining the two equations in the hint gives $pc = \sqrt{K(K+2mc^2)}$ and $\lambda = \dfrac{hc}{\sqrt{K(K+2mc^2)}}$.

EXECUTE: **(a)** With $K = 3mc^2$ this becomes $\lambda = \dfrac{hc}{\sqrt{3mc^2(3mc^2+2mc^2)}} = \dfrac{h}{\sqrt{15}mc}$.

(b) (i) $K = 3mc^2 = 3(9.109\times10^{-31}\ \text{kg})(2.998\times10^8\ \text{m/s})^2 = 2.456\times10^{-13}\ \text{J} = 1.53\ \text{MeV}$

$$\lambda = \frac{h}{\sqrt{15}mc} = \frac{6.626\times10^{-34}\ \text{J}\cdot\text{s}}{\sqrt{15}(9.109\times10^{-31}\ \text{kg})(2.998\times10^8\ \text{m/s})} = 6.26\times10^{-13}\ \text{m}.$$

(ii) K is proportional to m, so for a proton $K = (m_\text{p}/m_\text{e})(1.53\ \text{MeV}) = 1836(1.53\ \text{MeV}) = 2810\ \text{MeV}$.

λ is proportional to $1/m$, so for a proton

$\lambda = (m_\text{e}/m_\text{p})(6.26\times10^{-13}\ \text{m}) = (1/1836)(6.26\times10^{-13}\ \text{m}) = 3.41\times10^{-16}\ \text{m}.$

EVALUATE: The proton has a larger rest mass energy so its kinetic energy is larger when $K = 3mc^2$. The proton also has larger momentum so has a smaller λ.

39.70. **IDENTIFY:** Apply the Heisenberg uncertainty principle. Consider only one component of position and momentum.

SET UP: $\Delta x \Delta p_x \geq \hbar/2$. Take $\Delta x \approx 5.0\times10^{-15}$ m. $K = E - mc^2$. For a proton, $m = 1.67\times10^{-27}$ kg.

EXECUTE: **(a)** $\Delta p_x = \dfrac{\hbar}{2\Delta x} = \dfrac{(1.055\times10^{-34}\ \text{J}\cdot\text{s})}{2(5.0\times10^{-15}\ \text{m})} = 1.1\times10^{-20}\ \text{kg}\cdot\text{m/s}.$

(b) $K = \sqrt{(pc)^2 + (mc^2)^2} - mc^2 = 3.3\times10^{-14}\ \text{J} = 0.21\ \text{MeV}.$

EVALUATE: **(c)** The result of part (b), about 2×10^5 eV, is many orders of magnitude larger than the potential energy of an electron in a hydrogen atom.

39.71. **(a) IDENTIFY** and **SET UP:** $\Delta x \Delta p_x \geq \hbar/2$. Estimate Δx as $\Delta x \approx 5.0\times10^{-15}$ m.

EXECUTE: Then the minimum allowed Δp_x is $\Delta p_x \approx \dfrac{\hbar}{2\Delta x} = \dfrac{1.055\times10^{-34}\ \text{J}\cdot\text{s}}{2(5.0\times10^{-15}\ \text{m})} = 1.1\times10^{-20}\ \text{kg}\cdot\text{m/s}.$

(b) IDENTIFY and **SET UP:** Assume $p \approx 1.1\times10^{-20}$ kg · m/s. Use $E^2 = (mc^2)^2 + (pc)^2$ to calculate E, and then $K = E - mc^2$.

EXECUTE: $E = \sqrt{(mc^2)^2 + (pc)^2}$. $mc^2 = (9.109\times10^{-31}\ \text{kg})(2.998\times10^8\ \text{m/s})^2 = 8.187\times10^{-14}\ \text{J}.$

$pc = (1.1\times10^{-20}\ \text{kg}\cdot\text{m/s})(2.998\times10^8\ \text{m/s}) = 3.165\times10^{-12}\ \text{J}.$

$E = \sqrt{(8.187\times10^{-14}\ \text{J})^2 + (3.165\times10^{-12}\ \text{J})^2} = 3.166\times10^{-12}\ \text{J}.$

$K = E - mc^2 = 3.166\times10^{-12}\ \text{J} - 8.187\times10^{-14}\ \text{J} = 3.084\times10^{-12}\ \text{J}\times(1\ \text{eV}/1.602\times10^{-19}\ \text{J}) = 19\ \text{MeV}.$

(c) IDENTIFY and **SET UP:** The Coulomb potential energy for a pair of point charges is given by $U = -kq_1q_2/r$. The proton has charge $+e$ and the electron has charge $-e$.

EXECUTE: $U = -\dfrac{ke^2}{r} = -\dfrac{(8.988\times10^9\ \text{N}\cdot\text{m}^2/\text{C}^2)(1.602\times10^{-19}\ \text{C})^2}{5.0\times10^{-15}\ \text{m}} = -4.6\times10^{-14}\ \text{J} = -0.29\ \text{MeV}.$

EVALUATE: The kinetic energy of the electron required by the uncertainty principle would be much larger than the magnitude of the negative Coulomb potential energy. The total energy of the electron would be large and positive and the electron could not be bound within the nucleus.

39.72. **IDENTIFY** and **SET UP:** $\Delta E \Delta t \geq \hbar/2$. Take the minimum uncertainty product, so $\Delta E = \dfrac{\hbar}{2\Delta t}$, with $\Delta t = 8.4\times10^{-17}$ s. $m = 264m_e$. $\Delta m = \dfrac{\Delta E}{c^2}$.

EXECUTE: $\Delta E = \dfrac{1.055\times10^{-34}\ \text{J}\cdot\text{s}}{2(8.4\times10^{-17}\ \text{s})} = 6.28\times10^{-19}\ \text{J}$. $\Delta m = \dfrac{6.28\times10^{-19}\ \text{J}}{(3.00\times10^8\ \text{m/s})^2} = 7.0\times10^{-36}\ \text{kg}.$

$$\frac{\Delta m}{m} = \frac{7.0\times10^{-36}\ \text{kg}}{(264)(9.11\times10^{-31}\ \text{kg})} = 2.9\times10^{-8}.$$

EVALUATE: The fractional uncertainty in the mass is very small.

39.73. **IDENTIFY** and **SET UP:** Use $\lambda = h/p$ to relate your wavelength and speed.

EXECUTE: **(a)** $\lambda = \dfrac{h}{mv}$, so $v = \dfrac{h}{m\lambda} = \dfrac{6.626\times10^{-34}\ \text{J}\cdot\text{s}}{(60.0\ \text{kg})(1.0\ \text{m})} = 1.1\times10^{-35}\ \text{m/s}.$

(b) $t = \dfrac{\text{distance}}{\text{speed}} = \dfrac{0.80\ \text{m}}{1.1\times10^{-35}\ \text{m/s}} = 7.3\times10^{34}\ \text{s}(1\ \text{y}/3.156\times10^7\ \text{s}) = 2.3\times10^{27}\ \text{y}.$

Since you walk through doorways much more quickly than this, you will not experience diffraction effects.

EVALUATE: A 1-kg object moving at 1 m/s has a de Broglie wavelength $\lambda = 6.6\times10^{-34}$ m, which is exceedingly small. An object like you has a very, very small λ at ordinary speeds and does not exhibit wavelike properties.

39.74. IDENTIFY: The transition energy E for the atom and the wavelength λ of the emitted photon are related by $E = \dfrac{hc}{\lambda}$. Apply the Heisenberg uncertainty principle in the form $\Delta E \Delta t \geq \dfrac{\hbar}{2}$.

SET UP: Assume the minimum possible value for the uncertainty product, so that $\Delta E \Delta t = \dfrac{\hbar}{2}$.

EXECUTE: **(a)** $E = 2.58\text{ eV} = 4.13\times10^{-19}$ J, with a wavelength of $\lambda = \dfrac{hc}{E} = 4.82\times10^{-7}\text{m} = 482$ nm.

(b) $\Delta E = \dfrac{\hbar}{2\Delta t} = \dfrac{(1.055\times10^{-34}\text{ J}\cdot\text{s})}{2(1.64\times10^{-7}\text{ s})} = 3.22\times10^{-28}\text{ J} = 2.01\times10^{-9}$ eV.

(c) $\lambda E = hc$, so $(\Delta\lambda)E + \lambda\Delta E = 0$, and $|\Delta E/E| = |\Delta\lambda/\lambda|$, so

$$\Delta\lambda = \lambda|\Delta E/E| = (4.82\times10^{-7}\text{ m})\left(\frac{3.22\times10^{-28}\text{ J}}{4.13\times10^{-19}\text{ J}}\right) = 3.75\times10^{-16}\text{ m} = 3.75\times10^{-7}\text{ nm}.$$

EVALUATE: The finite lifetime of the excited state gives rise to a small spread in the wavelength of the emitted light.

39.75. IDENTIFY: Assume both the x rays and electrons are at normal incidence and scatter from the surface plane of the crystal, so the maxima are located by $d\sin\theta = m\lambda$, where d is the separation between adjacent atoms in the surface plane.

SET UP: Let primed variables refer to the electrons. $\lambda' = \dfrac{h}{p'} = \dfrac{h}{\sqrt{2mE'}}$.

EXECUTE: $\sin\theta' = \dfrac{\lambda'}{\lambda}\sin\theta$, and $\lambda' = (h/p') = (h/\sqrt{2mE'})$, and so $\theta' = \arcsin\left(\dfrac{h}{\lambda\sqrt{2mE'}}\sin\theta\right)$.

$$\theta' = \arcsin\left(\frac{(6.63\times10^{-34}\text{ J}\cdot\text{s})(\sin 35.8°)}{(3.00\times10^{-11}\text{ m})\sqrt{2(9.11\times10^{-31}\text{ kg})(4.50\times10^{+3}\text{ eV})(1.60\times10^{-19}\text{ J/eV})}}\right) = 20.9°.$$

EVALUATE: The x rays and electrons have different wavelengths and the $m = 1$ maxima occur at different angles.

39.76. IDENTIFY: The photon is emitted as the atom returns to the lower energy state. The duration of the excited state limits the energy of that state due to the uncertainty principle.

SET UP: The wavelength λ of the photon is related to the transition energy E of the atom by $E = \dfrac{hc}{\lambda}$.

$\Delta E\,\Delta t \geq \hbar/2$. The minimum uncertainty in energy is $\Delta E \geq \dfrac{\hbar}{2\Delta t}$.

EXECUTE: **(a)** The photon energy equals the transition energy of the atom, 3.50 eV.

$$\lambda = \frac{hc}{E} = \frac{(4.136\times10^{-15}\text{ eV}\cdot\text{s})(3.00\times10^{8}\text{ m/s})}{3.50\text{ eV}} = 355\text{ nm}.$$

(b) $\Delta E = \dfrac{1.055\times10^{-34}\text{ J}\cdot\text{s}}{2(2.0\times10^{-6}\text{ s})} = 2.6\times10^{-29}\text{ J} = 1.6\times10^{-10}$ eV.

EVALUATE: The uncertainty in the energy could be larger than that found in (b), but never smaller.

39.77. IDENTIFY: The wave (light or electron matter wave) having less energy will cause less damage to the virus.

SET UP: For a photon $E_{\text{ph}} = \dfrac{hc}{\lambda} = \dfrac{1.24\times10^{-6}\ \text{eV}\cdot\text{m}}{\lambda}$. For an electron $E_{\text{e}} = \dfrac{p^2}{2m} = \dfrac{h^2}{2m\lambda^2}$.

EXECUTE: **(a)** $E = \dfrac{hc}{\lambda} = \dfrac{1.24\times10^{-6}\ \text{eV}\cdot\text{m}}{5.00\times10^{-9}\ \text{m}} = 248\ \text{eV}.$

(b) $E_{\text{e}} = \dfrac{h^2}{2m\lambda^2} = \dfrac{(6.63\times10^{-34}\ \text{J}\cdot\text{s})^2}{2(9.11\times10^{-31}\ \text{kg})(5.00\times10^{-9}\ \text{m})^2} = 9.65\times10^{-21}\ \text{J} = 0.0603\ \text{eV}.$

EVALUATE: The electron has much less energy than a photon of the same wavelength and therefore would cause much less damage to the virus.

39.78. **IDENTIFY** and **SET UP:** Assume $px \approx h$ and use this to express E as a function of x. E is a minimum for that x that satisfies $\dfrac{dE}{dx} = 0.$

EXECUTE: **(a)** Using the given approximation, $E = \dfrac{1}{2}\left[(h/x)^2/m + kx^2\right]$, so $(dE/dx) = kx - (h^2/mx^3)$, and the minimum energy occurs when $kx = (h^2/mx^3)$, or $x^2 = \dfrac{h}{\sqrt{mk}}$. The minimum energy is then $h\sqrt{k/m}$.

EVALUATE: **(b)** $U = \frac{1}{2}kx^2 = \dfrac{h}{2}\sqrt{\dfrac{k}{m}}$. $K = \dfrac{p^2}{2m} = \dfrac{h^2}{2mx^2} = \dfrac{h}{2}\sqrt{\dfrac{k}{m}}$. At this x the kinetic and potential energies are the same.

39.79. **(a) IDENTIFY** and **SET UP:** $U = A|x|$. $F_x = -dU/dx$ relates force and potential. The slope of the function $A|x|$ is not continuous at $x = 0$, so we must consider the regions $x > 0$ and $x < 0$ separately.

EXECUTE: For $x > 0, |x| = x$, so $U = Ax$ and $F = -\dfrac{d(Ax)}{dx} = -A$. For $x < 0$, $|x| = -x$, so $U = -Ax$ and $F = -\dfrac{d(-Ax)}{dx} = +A$. We can write this result as $F = -A|x|/x$, valid for all x except for $x = 0$.

(b) IDENTIFY and **SET UP:** Use the uncertainty principle, expressed as $\Delta p \Delta x \approx h$, and as in Problem 39.78 estimate Δp by p and Δx by x. Use this to write the energy E of the particle as a function of x. Find the value of x that gives the minimum E and then find the minimum E.

EXECUTE: $E = K + U = \dfrac{p^2}{2m} + A|x|.$

$$px \approx h, \text{so } p \approx h/x.$$

Then $E \approx \dfrac{h^2}{2mx^2} + A|x|.$

For $x > 0, E = \dfrac{h^2}{2mx^2} + Ax.$

To find the value of x that gives minimum E set $\dfrac{dE}{dx} = 0.$

$$0 = \frac{-2h^2}{2mx^3} + A.$$

$$x^3 = \frac{h^2}{mA} \text{ and } x = \left(\frac{h^2}{mA}\right)^{\frac{1}{3}}.$$

With this x the minimum E is

$$E = \frac{h^2}{2m}\left(\frac{mA}{h^2}\right)^{2/3} + A\left(\frac{h^2}{mA}\right)^{1/3} = \frac{1}{2}h^{2/3}m^{-1/3}A^{2/3} + h^{2/3}m^{-1/3}A^{2/3}.$$

$$E = \frac{3}{2}\left(\frac{h^2A^2}{m}\right)^{1/3}.$$

EVALUATE: The potential well is shaped like a V. The larger A is, the steeper the slope of U and the smaller the region to which the particle is confined and the greater is its energy. Note that for the x that minimizes E, $2K = U$.

39.80. **(a) IDENTIFY and SET UP:** Let the y-direction be from the thrower to the catcher, and let the x-direction be horizontal and perpendicular to the y-direction. A cube with volume $V = 125\text{ cm}^3 = 0.125\times10^{-3}\text{ m}^3$ has side length $l = V^{1/3} = (0.125\times10^{-3}\text{ m}^3)^{1/3} = 0.050\text{ m}$. Thus estimate Δx as $\Delta x \approx 0.050\text{ m}$. Use the uncertainty principle to estimate Δp_x.

EXECUTE: $\Delta x\Delta p_x \ge \hbar/2$ then gives $\Delta p_x \approx \dfrac{\hbar}{2\Delta x} = \dfrac{0.01055\text{ J}\cdot\text{s}}{2(0.050\text{ m})} = 0.11\text{ kg}\cdot\text{m/s}$. (The value of $\hbar$ in this other universe has been used.)

(b) IDENTIFY and SET UP: $\Delta x = (\Delta v_x)t$ is the uncertainty in the x-coordinate of the ball when it reaches the catcher, where t is the time it takes the ball to reach the second student.
Obtain Δv_x from Δp_x.

EXECUTE: The uncertainty in the ball's horizontal velocity is $\Delta v_x = \dfrac{\Delta p_x}{m} = \dfrac{0.11\text{ kg}\cdot\text{m/s}}{0.25\text{ kg}} = 0.42\text{ m/s}$.

The time it takes the ball to travel to the second student is $t = \dfrac{12\text{ m}}{6.0\text{ m/s}} = 2.0\text{ s}$. The uncertainty in the x-coordinate of the ball when it reaches the second student that is introduced by Δv_x is $\Delta x = (\Delta v_x)t = (0.42\text{ m/s})(2.0\text{ s}) = 0.84\text{ m}$. The ball could miss the second student by about 0.84 m.

EVALUATE: A game of catch would be very different in this universe. We don't notice the effects of the uncertainty principle in everyday life because h is so small.

39.81. **IDENTIFY and SET UP:** For hydrogen-like atoms (1 electron and Z protons), the energy levels are $E_n = (-13.60\text{ eV})Z^2/n^2$, with $n = 1$ for the ground state. The energy of a photon is $E = hc/\lambda$.

EXECUTE: **(a)** The least energy absorbed is between the ground state ($n = 1$) and the $n = 2$ state, which gives the longest wavelength. So $\Delta E_{1\to2} = hc/\lambda$. Using the energy levels for this atom, we have

$(-13.6\text{ eV})Z^2\left(\dfrac{1}{2^2} - \dfrac{1}{1^2}\right) = \dfrac{hc}{\lambda} \;\rightarrow\; (10.20\text{ eV})Z^2 = hc/\lambda$. Solving Z gives

$$Z = \sqrt{\frac{hc}{(10.20\text{ eV})\lambda}} = \sqrt{\frac{(4.136\times10^{-15}\text{ eV}\cdot\text{s})(2.998\times10^8\text{ m/s})}{(10.20\text{ eV})(13.56\times10^{-9}\text{ m})}} = 3.0.$$

(b) The next shortest wavelength is between the $n = 3$ and $n = 1$ states.

$$\Delta E_{1\to3} = (-13.6\text{ eV})(3)^2\left(\frac{1}{3^2} - \frac{1}{1^2}\right) = \frac{hc}{\lambda}.$$

Solving for λ gives
$\lambda = (4.136\times10^{-15}\text{ eV}\cdot\text{s})(2.998\times10^8\text{ m/s})/(108.8\text{ eV}) = 11.40\text{ nm}$.

(c) By energy conservation, $E_{\text{photon}} = E_{\text{ionization}} + K_{\text{el}}$. The ionization energy is the minimum energy to completely remove an electron from the atom, which is from the $n = 1$ state to the $n = \infty$ state. Therefore $E_{\text{ionization}} = (13.60\text{ eV})Z^2 = (13.60\text{ eV})(9)$. Therefore the kinetic energy of the electron is

$$K_{\text{el}} = E_{\text{photon}} - E_{\text{ionization}} = hc/\lambda - E_{\text{ionization}}.$$

$$K_{\text{el}} = (4.136\times10^{-15}\text{ eV}\cdot\text{s})(2.998\times10^8\text{ m/s})/(6.78\times10^{-9}\text{ m}) - (13.60\text{ eV})(9) = 60.5\text{ eV}.$$

EVALUATE: The energy levels for a $Z = 3$ atom are 9 times as great as for the comparable energy levels in hydrogen, so the wavelengths of the absorbed light are much shorter than they would be for comparable transitions in hydrogen.

39.82. IDENTIFY and SET UP: The kinetic energy of the electron is $K = eV_{ac}$. The first-order maximum in the Davisson-Germer experiment occurs when $d\sin\theta = \lambda$. The de Broglie wavelength of an electron is $\lambda = h/p$, and its kinetic energy is $K = p^2/2m$. Therefore its momentum is $p = \sqrt{2mK}$, which means its de Broglie wavelength can be expressed as $\lambda = h/\sqrt{2mK}$.

EXECUTE: **(a)** Figure 39.82 shows the graph of $\sin\theta$ versus $1/\sqrt{V_{ac}}$ for the data in the problem. The slope of the best-fit graph is 3.522 $V^{1/2}$.

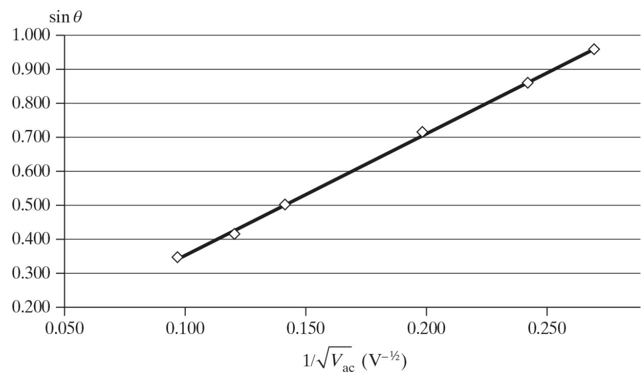

Figure 39.82

(b) At the first maximum, we have $d\sin\theta = \lambda = \dfrac{h}{p} = \dfrac{h}{\sqrt{2mK}} = \dfrac{h}{\sqrt{2meV_{ac}}}$, which we can write as $\sin\theta = \dfrac{h}{d\sqrt{2me}} \cdot \dfrac{1}{\sqrt{V_{ac}}}$. From this result, we see that a graph of $\sin\theta$ versus $1/\sqrt{V_{ac}}$ should be a straight line having slope equal to $\dfrac{h}{d\sqrt{2me}}$. Solving for d gives $d = \dfrac{h}{(\text{slope})\sqrt{2me}}$, which gives

$$d = \frac{4.136\times10^{-15}\ \text{J}\cdot\text{s}}{(3.522\ \text{V}^{1/2})\sqrt{2(9.11\times10^{-31}\ \text{kg})(1.60\times10^{-19}\ \text{C})}} = 3.48\times10^{-10}\ \text{m} = 0.348\ \text{nm}.$$

EVALUATE: Atom spacing in crystals are typically around a few tenths of a nanometer, so these results are plausible.

39.83. IDENTIFY and SET UP: The power radiated by an ideal blackbody is $P = \sigma AT^4$. Wien's displacement law, $\lambda_m T = 2.90\times10^{-3}\ \text{m}\cdot\text{K}$, applies to the stars. The surface area of a star is $A = 4\pi R^2$, and $R_{sun} = 6.96\times10^8$ m.

EXECUTE: **(a)** Calculate the radiated power for each star using $P = \sigma AT^4$. For Polaris we have $P = \sigma AT^4 = (5.67\times10^{-8}\ \text{W/m}^2\cdot\text{K}^4)(4\pi)[(46)(6.96\times10^8\ \text{m})]^2(6015\ \text{K})^4 = 9.56\times10^{29}$ W.

Repeating this calculation for the other stars gives us the following results.

Polaris: $P = 9.56\times10^{29}$ W
Vega: $P = 2.19\times10^{28}$ W
Antares: $P = 3.60\times10^{31}$ W
α Centauri B: $P = 1.98\times10^{26}$ W

Antares has the greatest radiated power.

(b) Apply Wien's displacement law, $\lambda_{\mathrm{m}}T = 2.90\times10^{-3}\ \mathrm{m}\cdot\mathrm{K},$ and solve for $\lambda_{\mathrm{m}}.$ For example, for Polaris we have $\lambda_{\mathrm{m}} = \dfrac{2.90\times10^{-3}\ \mathrm{m}\cdot\mathrm{K}}{T} = \dfrac{2.90\times10^{-3}\ \mathrm{m}\cdot\mathrm{K}}{6015\ \mathrm{K}} = 4.82\times10^{-7}\ \mathrm{m} = 482\ \mathrm{nm}.$ Repeating this calculation for the other stars gives the following results.

<u>Polaris</u>: λ_{m} = 482 nm
<u>Vega</u>: λ_{m} = 302 nm
<u>Antares</u>: λ_{m} = 853 nm
<u>α Centauri B</u>: λ_{m} = 551 nm

The visible range is 380 nm to 750 nm, so Polaris and α Centauri B radiate chiefly in the visible range.
(c) By comparing the results in part (a), we see that only α Centauri B radiates less than our sun.
EVALUATE: The power radiated by a star depends on its surface area *and* its surface temperature. Vega, a very hot star, radiates less than the much cooler Antares because Antares has over 300 times the radius of Vega and therefore over 300^2 times the surface area of Vega. A hot star is not necessarily brighter than a cool star.

39.84. **IDENTIFY:** This problem involves blackbody radiation and the Planck radiation law.
SET UP: We have r = 1.23 m and use Equation 39.24. The device captures all photons within 1% of the central peak E_0. For such a small range, we can treat the emittance as constant over

$$E_0 \pm \Delta E, \Delta E = 0.0100E_0.\ \ E = hc/\lambda,\ \ I(\lambda) = \frac{2\pi hc^2}{\lambda^5\left(e^{hc/\lambda kT}-1\right)},\ I = \int I(\lambda)\, d\,\lambda.$$

EXECUTE: **(a)** Restructure $\int I(\lambda)d\,\lambda$ as $\int I(E)\,dE.$ Using $E = hc/\lambda$ gives $d\lambda = -\lambda^2\,dE/hc.$

$$I = \int I(E)\,dE = \int \frac{2\pi hc^2\left(-\lambda^2\ dE/hc\right)}{\lambda^5\left(e^{E/kT}-1\right)} = -\int \frac{2\pi E^3}{h^3c^2\left(e^{e/kT}-1\right)}dE.$$

Therefore it follows that

$$I(E) = \frac{2\pi E^3}{h^3\,c^2\left(e^{E/kT}-1\right)}.$$

(b) We want to find the E_0 that maximizes $I(E)$ and then use it to find $I_{\mathrm{max}} = I(E_0)$. Set $dI(E)/dt = 0$ for a maximum, using the result from part (a). This gives $\dfrac{\left(e^{E/kT}-1\right)\left(3\,E^2\right) - E^3\left(1/kT\right)e^{E/kT}}{\left(e^{E/kT}-1\right)^2} = 0,$ which simplifies to $3 - 3\mathrm{e}^{-E/kT} - E/kT = 0.$

Letting $x = E/kT$, the final equation we must solve is $3 - x = 3e^{-x}$. Using trial-and-error (which gives an answer rather quickly) or appropriate software, the result is x = 2.821, so E/kT = 2.821, which gives $E_0 = 2.821kT$. Now use this result to find $I_{\mathrm{max}} = I(E_0)$, giving

$$I_{\mathrm{max}} = \frac{2\pi(2.821kT)^3}{h^3c^3(2.821-1)} = \frac{2.843\pi k^3T^3}{h^3c^2}.$$

(c) We want the power and current at T = 1000 K. At T = 1000 K, $E_0 = 2.821kT = 3.896\times10^{-20}$ J. The photocells capture all photons within 1% of E_0, so the full range of energy is $E_0 \pm 1\%E_0$, which is 2% E_0. So ΔE = (0.020)(3.896×10^{-20} J) = 7.792×10^{-22} J. $P = IA = I(E)(\Delta E)A$. Using given numbers and the values we have found gives

$$p = \left(\frac{2.843\pi k^3T^3}{h^3c^3}\right)(\Delta E)\left(4\pi r^2\right) = 13.3\ \mathrm{kW}.$$

Solving $P = I^2R$ for I and using this result gives I = 3.64 A.

(d) We want the power and current if $T = 5000$ K. Follow the same procedure as in part (c), giving $E_0 = 2.821kT = (2.821)k(5000\text{ K}) = 1.946 \times 10^{-19}$ J, $\Delta E = 0.020E_0 = 3.893 \times 10^{-21}$ J, $P = 8.29$ MW, and $I = 91.1$ A.

EVALUATE: In (c) and (d) we see that increasing the temperature by a factor of 5 increased the power by a factor of $5^4 = 625$ because the power is proportional to T^4.

39.85. **IDENTIFY:** We are looking at the energy and momentum in particle collision at nonrelativistic speeds. An alpha particle collides with a gold nucleus at rest.

SET UP: Energy and momentum are conserved during the collision. Use $K = p^2/2m$ to express p in terms of K.

EXECUTE: **(a)** We want V (the gold) speed. Energy conservation: $K = \frac{1}{2}mv^2 + \frac{1}{2}MV^2$. Momentum conservation: $\sqrt{2mK} = MV - mv$ Solving for V gives $V = \sqrt{8mK}/(m+M)$.

(b) We want $\Delta K(\alpha)/K$. The kinetic energy lost by the alpha particle is equal to the kinetic energy gained by the gold nucleus. Using this fact gives

$$\frac{\Delta K(\alpha)}{K(\alpha)} = \frac{\frac{1}{2}MV^2}{K} = \frac{\frac{1}{2}\left(\frac{\sqrt{8mK}}{m+M}\right)^2}{K} = \frac{4mM}{(m+M)^2}.$$

(c) From part (b) we know that the fractional energy lost depends only on the masses, so the result is *independent* of the initial kinetic energy. Therefore the answer is *yes*.

(d) We want V and the fractional energy lost to the gold if $K = 5.00$ MeV. Using the given numbers for m, M, and K in $V = \sqrt{8mK}/(m+M)$ from part (a) and converting 5.00 MeV to joules gives $V = 1.49 \times 10^6$ m/s $= 0.00497c$. From part (b), the fraction lost is $4mM/(m+M)^2 = 0.182 = 18.2\%$.

(e) We want v, so that $V = 0.10c$ by using nonrelativistic physics. First find K using $V = \sqrt{8mK}/(m+M)$, giving $K = [V(m+M)]^2/8m$. Classically, $K = \frac{1}{2}mv^2$. Equating this to the previous result and solving for v gives $v = V(1 + M/m)/2$. Using $V = 0.10c$ and the given masses gives $v = 1.04c$.

EVALUATE: **(f)** This speed is not possible, so we would need to use the relativistic equations.

39.86. **IDENTIFY:** Follow the steps specified in the hint.

SET UP: The value of Δx_i that minimizes Δx_f satisfies $\dfrac{d(\Delta x_f)}{d(\Delta x_i)} = 0.$

EXECUTE: Time of flight of the marble, from a free-fall kinematic equation is just $t = \sqrt{\dfrac{2y}{g}} = \sqrt{\dfrac{2(25.0\text{ m})}{9.80\text{ m/s}^2}} = 2.26$ s. $\Delta x_f = \Delta x_i + (\Delta v_x)t = \Delta x_i + \left(\dfrac{\Delta p_x}{m}\right)t = \dfrac{\hbar t}{2\Delta x_i m} + \Delta x_i$. To minimize Δx_f with respect to Δx_i, $\dfrac{d(\Delta x_f)}{d(\Delta x_i)} = 0 = \dfrac{-\hbar t}{2m(\Delta x_i)^2} + 1 \Rightarrow \Delta x_i(\text{min}) = \sqrt{\left(\dfrac{\hbar t}{2m}\right)}$

$$\Rightarrow \Delta x_f(\text{min}) = \sqrt{\frac{\hbar t}{2m}} + \sqrt{\frac{\hbar t}{2m}} = \sqrt{\frac{2\hbar t}{m}} = \sqrt{\frac{2(1.055\times 10^{-34}\text{ J}\cdot\text{s})(2.26\text{ s})}{0.0200\text{ kg}}} = 1.54\times 10^{-16}\text{ m}$$

$$= 1.54\times 10^{-7}\text{ nm}.$$

EVALUATE: The uncertainty introduced by the uncertainty principle is completely negligible in this situation.

39.87. **IDENTIFY** and **SET UP:** The period was found in Exercise 39.23b: $T = \dfrac{4\epsilon_0^2 n^3 h^3}{me^4}$. The equation

$E_n = -\dfrac{1}{\epsilon_0^2}\dfrac{me^4}{8n^2h^2}$ gives the energy of state n of a hydrogen atom.

EXECUTE: **(a)** The frequency is $f = \dfrac{1}{T} = \dfrac{me^4}{4\epsilon_0^2 n^3 h^3}$.

(b) The equation $hf = E_\text{i} - E_\text{f}$ tells us that $f = \dfrac{1}{h}(E_2 - E_1)$. So $f = \dfrac{me^4}{8\epsilon_0^2 h^3}\left(\dfrac{1}{n_2^2} - \dfrac{1}{n_1^2}\right)$. If $n_2 = n$ and $n_1 = n+1$, then $\dfrac{1}{n_2^2} - \dfrac{1}{n_1^2} = \dfrac{1}{n^2} - \dfrac{1}{(n+1)^2} = \dfrac{1}{n^2}\left(1 - \dfrac{1}{(1+1/n)^2}\right) \approx \dfrac{1}{n^2}\left(1 - \left(1 - \dfrac{2}{n} + \dots\right)\right) = \dfrac{2}{n^3}$. Therefore, for large n, $f \approx \dfrac{me^4}{4\epsilon_0^2 n^3 h^3}$.

EVALUATE: We have shown that for large n we obtain the classical result that the frequency of revolution of the electron is equal to the frequency of the radiation it emits.

39.88. **IDENTIFY** and **SET UP:** The de Broglie wavelength of the helium is $\lambda = h/p$. Its kinetic energy is $K = p^2/2m$, so $p = \sqrt{2mK}$. Therefore its de Broglie wavelength can be expressed as $\lambda = h/\sqrt{2mK}$. The kinetic energy of the ions acquired during acceleration is $K = eV = p^2/2m$.

EXECUTE: Express the wavelength in terms of V, giving $\lambda = h/\sqrt{2mK} = h/\sqrt{2meV}$. From this we see that a large mass m results in a small (short) wavelength, which is choice (b).

EVALUATE: Because helium is 7300 times heavier than an electron and because $\lambda \propto 1/\sqrt{m}$, the wavelength for helium would be $1/\sqrt{7300} = 0.012$ times the wavelength of an electron.

39.89. **IDENTIFY:** Calculate the accelerating potential V need to produce a helium ion with a wavelength of 0.1 pm to see if that potential lies within the range of 10-50 kV.

SET UP: The de Broglie wavelength of the helium ion is $\lambda = h/p$, so $p = h/\lambda$. By energy conservation, $K = eV = p^2/2m$.

EXECUTE: Combining the above equations gives

$$eV = K = p^2/2m = \frac{(h/\lambda)^2}{2m}, \text{ so } V = \frac{(h/\lambda)^2}{2me}.$$

$$V = \frac{\left[(6.626\times10^{-34}\text{ J}\cdot\text{s})/(0.1\times10^{-12}\text{ m})\right]^2}{2(7300)(9.11\times10^{-31}\text{ kg})(1.60\times10^{-19}\text{ C})} = 2.1\times10^4\text{ V} = 21\text{ kV}.$$

This voltage is within the 10-50 kV range, so choice (a) is correct.

EVALUATE: A large voltage is required because the desired wavelength is small.

39.90. **IDENTIFY** and **SET UP:** Electric and magnetic fields act on electrical charges.

EXECUTE: Focusing particles requires electric and magnetic forces, so they must have charge, which makes choice (c) correct.

EVALUATE: All particles have wave properties, so choice (a) is not correct. Helium is an inert gas, so it normally does form molecules, so that rules out choice (b). The mass difference between a helium atom and a helium ion is negligible because the electron is 7300 times lighter than a helium ion, which eliminates choice (d).

39.91. **IDENTIFY** and **SET UP:** The ion loses 0.2 MeV/μm, and its energy can be determined only to within 6 keV. Call x the minimum difference in thickness that can be discerned, and realize that 0.2 MeV = 200 keV.

EXECUTE: (0.2 MeV/μm)x = 6 keV. Solving for x gives x = (6 keV)/(200 keV/μm) = 0.03 μm, which makes choice (a) the correct one.

EVALUATE: Greater precision in determining the energy of the ion would allow one to discern smaller features.

40

QUANTUM MECHANICS I: WAVE FUNCTIONS

VP40.4.1. **IDENTIFY:** This problem involves an electron in a one-dimensional box.

SET UP: $E_n = n^2 \dfrac{\pi^2 \hbar^2}{8mL^2}.$

EXECUTE: **(a)** We want the width L of the box. Solve the energy equation for L with $n = 1$ and use the given energy for E_1. $L = \dfrac{h}{\sqrt{8mE_1}} = 0.549$ nm.

(b) We want the energy. Use $E_n = n^2 E_1$ with the given energy for E_1. $E_2 = 2^2 E_1 = 4(2.00 \times 10^{-19}\text{ J})$ $= 8.00 \times 10^{-19}$ J. $E_3 = 3^2(2.00 \times 10^{-19}\text{ J}) = 1.80 \times 10^{-19}$ J.

EVALUATE: Note that the energy levels are not evenly spaced.

VP40.4.2. **IDENTIFY:** This problem involves an electron in a one-dimensional box.

SET UP: $E_n = n^2 \dfrac{\pi^2 \hbar^2}{8mL^2}$. We want the energy difference between levels.

EXECUTE: **(a)** Using the energy equation, the energy difference between levels is

$$\Delta E_{2,1} = \frac{h^2}{8mL^2}\left(2^2 - 1^2\right) = \frac{3h^2}{8mL^2} = \frac{3h^2}{8m\left(5.00 \times 10^{-15}\text{ m}\right)^2} = 3.94 \times 10^{-12}\text{ J}.$$

(b) Using the same equation as in part (a) gives

$$\Delta E_{2,1} = \frac{h^2}{8mL^2}\left(3^2 - 2^2\right) = \frac{5h^2}{8mL^2} = 6.57 \times 10^{-12}\text{ J}.$$

EVALUATE: Note that the energy difference between adjacent levels increases as the levels increase to higher values of n.

VP40.4.3. **IDENTIFY:** This problem involves transitions by an electron in a one-dimensional box.

SET UP: $E_n = n^2 \dfrac{\pi^2 \hbar^2}{8mL^2}$, $E = hc/\lambda$.

EXECUTE: **(a)** We want the energy of the photon. $E = hc/\lambda = hc/(655\text{ nm}) = 3.03 \times 10^{-19}$ J.

(b) We want the length L of the box. The energy of the photon is equal to the energy difference between the $n = 1$ and $n = 2$ levels.

$$E_{\text{ph}} = \frac{h^2}{8mL^2}\left(2^2 - 1^2\right) = \frac{3h^2}{8mL^2}.$$

Solve for L using the photon energy from part (a), giving $L = 0.772$ nm.

(c) We want the wavelength of the photon. The energy of the photon is the energy difference between the $n = 2$ and $n = 3$ levels. Use $E = hc/\lambda$ and $L = 0.772$ nm and solve for λ.

$$E_{\text{ph}} = \frac{h^2}{8mL^2}\left(3^2 - 2^2\right) = \frac{5h^2}{8mL^2} = \frac{hc}{\lambda}. \quad \lambda = \frac{8mL^2c}{5h} = 393 \text{ nm}.$$

EVALUATE: Note that the wavelength for the $3 \to 2$ transition is less than the wavelength for the $2 \to 1$ transition. This result is reasonable because the energy difference is greater for the $3 \to 2$ transition than it is for the $2 \to 1$ transition.

VP40.4.4. **IDENTIFY:** This problem involves the wave function for a particle in a box.

SET UP: The wave function and Schrödinger equation are

$$\psi(x) = A\cos\left(\frac{x\sqrt{2mE}}{\hbar} + \phi\right), -\frac{\hbar^2}{2m}\frac{d^2\psi}{dx} = E\psi.$$

EXECUTE: **(a)** We want to show that the given wave function satisfied the Schrödinger equation. First take the second derivative of the wave function and then multiply it by $-\hbar^2/2m$.

$$\frac{d^2\psi}{dx^2} = -\frac{A(2mE)}{\hbar^2}\cos\left(\frac{x\sqrt{2mE}}{\hbar} + \phi\right) - \frac{\hbar^2}{2m}\frac{d^2\psi}{dx^2} = -\frac{\hbar^2}{2m}\left(-\frac{A(2mE)}{\hbar^2}\right)\cos\left(\frac{x\sqrt{2mE}}{\hbar} + \phi\right)$$

$$= EA\cos\left(\frac{x\sqrt{2mE}}{\hbar} + \phi\right) = E\psi.$$

(b) We want ϕ. The wave function must be zero at $x = 0$, which gives $\cos\phi = 0$, so $\phi = \pm\pi/2$.

(c) We want E. At $x = L$ the wave function must be zero, which gives

$$A\cos\left(\frac{L\sqrt{2mE}}{\hbar} \pm \frac{\pi}{2}\right) = 0. \quad \frac{L\sqrt{2mE}}{\hbar} \pm \frac{\pi}{2} = \frac{\pi}{2}.$$

L cannot be zero, so we must have

$$\frac{L\sqrt{2mE_n}}{\hbar} = n\pi. \quad E_n = n^2\frac{\pi^2\hbar^2}{2mL^2}, n = 1, 2, 3, \cdots$$

EVALUATE: The result in part (c) agrees with Eq. (40.31) in the text.

VP40.6.1. **IDENTIFY:** We are dealing with an electron in a finite potential well.

SET UP: For an infinitely deep well the energy levels are

$$E_{n\text{-IDW}} = n^2\frac{\pi^2\hbar^2}{2mL^2}$$

and for a finite well we use Figure 40.15 in the textbook.

EXECUTE: **(a)** We want the ground level energy, so $n = 1$.

$$E_{\text{1-IDW}} = \frac{\pi^2\hbar^2}{2mL^2} = \frac{\pi^2\hbar^2}{2m(0.350 \text{ nm})^2} = 4.92\times10^{-19} \text{ J}.$$

(b) We want the ground level energy. In this case, $U_0 = 6E_{\text{1-IDW}}$. From Figure 40.15b in the text, we see that $E_1 = 0.625E_{\text{1-IDW}}$, which gives

$E_1 = (0.625)(4.92\times10^{-19} \text{ J}) = 3.07\times10^{-19}$ J.

(c) We want the minimum energy to free the electron. The electron already has 3.07×10^{-19} J of energy, and to be free it needs to have a minimum of $U_0 = 6E_{\text{1-IDW}} = 6(4.92\times10^{-19} \text{ J}) = 2.95\times10^{-18}$ J.

So, the additional energy it needs is $U_0 - E_1 = 2.64\times10^{-18}$ J.

EVALUATE: If the well were infinite, the electron would need infinite energy to escape, meaning that it could not escape.

VP40.6.2. **IDENTIFY:** We are dealing with particle in a finite potential well.

SET UP: $U_0 = 6E_{\text{1-IDW}}$, the energy difference between the $n = 2$ and $n = 3$ levels is the energy of the photon. Refer to Figure 40.15 in the textbook.

EXECUTE: **(a)** We want $E_{\text{1-IDW}}$. Figure 40.15b, shows that $E_3 = 5.09E_{\text{1-IDW}}$ and $E_2 = 2.43E_{\text{1-IDW}}$. The energy difference between these levels is $E_3 - E_2 = (5.09 - 2.43)E_{\text{1-IDW}} = 2.50 \times 10^{-19}$ J, which gives $E_{\text{1-IDW}} = 9.40 \times 10^{-20}$ J.

(b) We want U_0. $U_0 = 6E_{\text{1-IDW}} = 6(9.40 \times 10^{-20}\text{ J}) = 5.64 \times 10^{-19}$ J.

(c) We want the width L of the well. Solve $E_{\text{1-IDW}} = n^2h^2/8mL^2$ for L and use the result from part (b) with $n = 1$. This gives $L = 0.800$ nm.

EVALUATE: The ground state energy of this well is $(0.625)E_{\text{1-IDW}} = 5.88 \times 10^{-20}$ J.

VP40.6.3. **IDENTIFY:** We are dealing with an electron in a finite potential well.

SET UP: $U_0 = 6E_{\text{1-IDW}}$, $E = hc/\lambda$. Use Figure 40.15 in the textbook.

EXECUTE: **(a)** We want the initial and final energy levels. In this case, there are only three possible transitions: $3 \to 2$, $2 \to 1$, and $3 \to 1$. The greatest energy difference is from the $3 \to 1$ transition which emits a photon of the shortest wavelength. So the initial state is $n = 3$ and the final state is $n = 1$.

(b) Figure 40.15b in the textbook gives $E_3 = 5.09E_{\text{1-IDW}}$ and $E_1 = 0.625E_{\text{1-IDW}}$. Therefore the energy of the photon is $E_3 - E_1 = (5.09 - 0625)E_{\text{1-IDW}} = 4.465E_{\text{1-IDW}}$. Using $E = hc/\lambda$ with the 355 nm wavelength and solving for $E_{\text{1-IDW}}$ gives $E_{\text{1-IDW}} = hc/[(4.465)(355\text{ nm})]$.

<u>$3 \to 2$ transition</u>: The energy difference is $(5.09 - 2.43)E_{\text{1-IDW}}$, and this is the photon energy.

$$\frac{hc}{\lambda_{3\to2}} = 2.66E_{\text{1-IDW}} = (2.66)\frac{hc}{(4.465)(355\text{ nm})}.\ \lambda_{3\to2} = 596\text{ nm}.$$

<u>$2 \to 1$ transition</u>: The energy difference is $(2.43 - 0.625)E_{\text{1-IDW}}$, and this is the photon energy.

$$\frac{hc}{\lambda_{2\to1}} = 1.805E_{\text{1-IDW}} = (1.805)\frac{hc}{(4.465)(355\text{ nm})}.\ \lambda_{2\to1} = 878\text{ nm}.$$

EVALUATE: As the energy difference between the levels gets larger, the photon wavelength gets shorter, which is physically reasonable.

VP40.6.4. **IDENTIFY:** We are dealing with an electron in a finite potential well.

SET UP: $E_{\text{1-IDW}} = \dfrac{\pi^2\hbar^2}{2mL^2}$.

EXECUTE: **(a)** We want the ground level energy for an infinite well. Using $L = 0.400$ nm and the equation for $E_{\text{1-IDW}}$ gives 2.35 eV.

(b) We want the energy of the bound state if $U_0 = 0.015$ eV. Because $U_0 \ll E_{\text{1-IDW}}$, $E = 0.68U_0$. Therefore $E = (0.68)(0.015\text{ eV}) = 0.010$ eV.

EVALUATE: The energy of the bound state is much less than the ground level for an infinite well of the same length.

VP40.7.1. **IDENTIFY:** This problem is about an electron tunneling through a potential barrier. We want the probability that the electron will tunnel through barriers if different thicknesses if its energy is 3.75 eV and the barrier height is 6.10 eV.

SET UP: The probability T of tunneling us $T = Ge^{-2\kappa L}$, where

$$G = 16\frac{E}{U_0}\left(1 - \frac{E}{U_0}\right) \text{ and } \kappa = \frac{\sqrt{2m(U_0 - E)}}{\hbar}.$$

EXECUTE: **(a)** $L = 0.750$ nm. First calculate G and κ and then use them to find T.

$$G = 16\left(\frac{3.75\text{ eV}}{6.10\text{ eV}}\right)\left(1 - \frac{3.75\text{ eV}}{6.10\text{ eV}}\right) = 3.7893,\quad \kappa = \frac{\sqrt{2m(6.10 - 3.75)\text{ eV}}}{\hbar} = 7.85005 \times 10^9\text{ m}^{-1}$$

Using these values gives $T = (3.789)e^{-11.763} = 2.92 \times 10^{-5}$.
(b) $L = 0.500$ nm. We get $T = (3.789)e^{-7.85005} = 1.48 \times 10^{-3}$.
EVALUATE: It is about 50 times more likely that the electron will tunnel through the narrower barrier than through the wider one. But probabilities are very low.

VP40.7.2. **IDENTIFY:** This problem is about an electron tunneling through a potential barrier.
SET UP: The probability T of tunneling us $T = Ge^{-2\kappa L}$, where

$$G = 16\frac{E}{U_0}\left(1 - \frac{E}{U_0}\right) \text{ and } \kappa = \sqrt{\frac{2m(U_0 - E)}{\hbar}}.$$

EXECUTE: **(a)** We want T when $L = 0.800$ nm. First calculate G and κ and then use them to find T.

$$G = 16\left(\frac{3.50\text{ eV}}{4.00\text{ eV}}\right)\left(1 - \frac{3.50\text{ eV}}{4.00\text{ eV}}\right) = 1.7500,\quad \kappa = \frac{\sqrt{2m(4.00 - 3.50)\text{ eV}}}{\hbar} = 3.62096 \times 10^9\text{ m}^{-1}.$$

Using these values gives $T = (1.7500)e^{-5.79354} = 5.33 \times 10^{-3}$.
(b) We want L, so that the probability of tunneling is twice as great as in part (a). Solve $T = Ge^{-2\kappa L}$ for L. G and κ are the same as in part (a). Taking natural logarithms gives $L = -(1/2\kappa)\ln(T/G)$. Using G and κ with T twice what we found in part (a), we get $L = 0.704$ nm.
EVALUATE: Decreasing the width of the barrier from 0.800 nm to 0.704 nm doubled the probability of tunneling.

VP40.7.3. **IDENTIFY:** This problem is about an electron tunneling through a potential barrier. We want to find the probability of tunneling for different energies of the electron with $U_0 = 5.00\text{ eV}$ and $L = 0.900$ nm.
SET UP: The probability T of tunneling us $T = Ge^{-2\kappa L}$, where

$$G = 16\frac{E}{U_0}\left(1 - \frac{E}{U_0}\right) \text{ and } \kappa = \frac{\sqrt{2m(U_0 - E)}}{\hbar}.$$

EXECUTE: **(a)** $E = 4.00$ eV. We want T when $L = 0.800$ nm. First calculate G and κ and then use them to find T.

$$G = 16\left(\frac{3.50\text{ eV}}{4.00\text{ eV}}\right)\left(1 - \frac{3.50\text{ eV}}{4.00\text{ eV}}\right) = 1.7500,\quad \kappa = \frac{\sqrt{2m(4.00 - 3.50)\text{ eV}}}{\hbar} = 3.62096 \times 10^9\text{ m}^{-1}$$

Using these values gives $T = (1.7500)e^{-5.79354} = 5.33 \times 10^{-3}$.
(b) $E = 4.30$ eV. $G = 1.9264$, $\kappa = 4.2844 \times 10^9\text{ m}^{-1}$, $T = (1.9264)e^{-7.71188} = 8.62 \times 10^{-4}$.
(c) $E = 4.60$ eV. $G = 1.1776$, $\kappa = 3.23868 \times 10^9\text{ m}^{-1}$, $T = (1.1776)e^{-5.82963} = 3.46 \times 10^{-3}$.
EVALUATE: Our results show that as E gets closer to the height of the potential barrier, the probability of tunneling increases, which is physically reasonable.

VP40.7.4. **IDENTIFY:** This problem is about an electron tunneling through a potential barrier. We want to find the width L of the barrier if there is a 1/417 probability that the electron will tunnel through the barrier if the electron's energy is 3.00 eV and the barrier height is 5.00 eV.
SET UP: The probability T of tunneling us $T = Ge^{-2\kappa L}$, where

$$G = 16\frac{E}{U_0}\left(1 - \frac{E}{U_0}\right) \text{ and } \kappa = \frac{\sqrt{2m(U_0 - E)}}{\hbar}.$$

EXECUTE: Solve $T = Ge^{-2\kappa L}$ for L. Taking natural logarithms gives $L = -(1/2\kappa)\ln(T/G)$.

$$G = 16\left(\frac{3.00\text{ eV}}{5.00\text{ eV}}\right)\left(1 - \frac{3.00\text{ eV}}{5.00\text{ eV}}\right) = 3.8400,\ \kappa = \frac{\sqrt{2m(5.00 - 3.00)\text{ eV}}}{\hbar} = 7.24192 \times 10^9\text{ m}^{-1}.$$

Using $T = 1/417$ and the G and κ we just calculated gives $L = 0.509$ nm.
EVALUATE: The value of L is comparable to atomic dimensions.

40.1. IDENTIFY: Using the momentum of the free electron, we can calculate k and ω and use these to express its wave function.

SET UP: $\Psi(x,t)=Ae^{ikx}e^{-i\omega t}$, $k=p/\hbar$, and $\omega=\hbar k^2/2m$.

EXECUTE: $k=\dfrac{p}{\hbar}=-\dfrac{4.50\times10^{-24}\ \text{kg}\cdot\text{m/s}}{1.055\times10^{-34}\ \text{J}\cdot\text{s}}=-4.27\times10^{10}\ \text{m}^{-1}$.

$$\omega=\frac{\hbar k^2}{2m}=\frac{(1.055\times10^{-34}\ \text{J}\cdot\text{s})(4.27\times10^{10}\ \text{m}^{-1})^2}{2(9.108\times10^{-31}\ \text{kg})}=1.05\times10^{17}\ \text{s}^{-1}.$$

$$\Psi(x,t)=Ae^{-i(4.27\times10^{10}\ \text{m}^{-1})x}e^{-i(1.05\times10^{17}\ \text{s}^{-1})t}.$$

EVALUATE: The wave function depends on position and time.

40.2. IDENTIFY: Using the known wave function for the particle, we want to find where its probability function is a maximum.

SET UP: $|\Psi(x,t)|^2=|A|^2(e^{ikx}e^{-i\omega t}-e^{2ikx}e^{-4i\omega t})(e^{-ikx}e^{+i\omega t}-e^{-2ikx}e^{+4i\omega t})$.

$|\Psi(x,t)|^2=|A|^2\left[2-(e^{-i(kx-3\omega t)}+e^{+i(kx-3\omega t)})\right]=2|A|^2[1-\cos(kx-3\omega t)]$.

EXECUTE: **(a)** For $t=0$, $|\Psi(x,t)|^2=2|A|^2(1-\cos(kx))$. $|\Psi(x,t)|^2$ is a maximum when $\cos(kx)=-1$ and this happens when $kx=(2n+1)\pi,\ n=0,1,\ldots$. $|\Psi(x,t)|^2$ is a maximum for $x=\dfrac{\pi}{k},\dfrac{3\pi}{k}$, etc.

(b) $t=\dfrac{2\pi}{\omega}$ and $3\omega t=6\pi$. $|\Psi(x,t)|^2=2|A|^2[1-\cos(kx-6\pi)]$. Maximum for $kx-6\pi=\pi,3\pi,\ldots$, which gives maxima when $x=\dfrac{7\pi}{k},\dfrac{9\pi}{k}$.

(c) From the results for parts (a) and (b), $v_{\text{av}}=\dfrac{7\pi/k-\pi/k}{2\pi/\omega}=\dfrac{3\omega}{k}$. $v_{\text{av}}=\dfrac{\omega_2-\omega_1}{k_2-k_1}$ with $\omega_2=4\omega$, $\omega_1=\omega$, $k_2=2k$ and $k_1=k$ gives $v_{\text{av}}=\dfrac{3\omega}{k}$.

EVALUATE: The expressions in part (c) agree.

40.3. IDENTIFY: Use the wave function from Example 40.1.

SET UP: $|\Psi(x,t)|^2=2|A|^2\{1+\cos[(k_2-k_1)x-(\omega_2-\omega_1)t]\}$. $k_2=3k_1=3k$. $\omega=\dfrac{\hbar k^2}{2m}$, so $\omega_2=9\omega_1=9\omega$.

$|\Psi(x,t)|^2=2|A|^2[1+\cos(2kx-8\omega t)]$.

EXECUTE: **(a)** At $t=2\pi/\omega$, $|\Psi(x,t)|^2=2|A|^2[1+\cos(2kx-16\pi)]$. $|\Psi(x,t)|^2$ is maximum for $\cos(2kx-16\pi)=1$. This happens for $2kx-16\pi=0,2\pi,\ldots$. Smallest positive x where $|\Psi(x,t)|^2$ is a maximum is $x=\dfrac{8\pi}{k}$.

(b) From the result of part (a), $v_{\text{av}}=\dfrac{8\pi/k}{2\pi/\omega}=\dfrac{4\omega}{k}$. $v_{\text{av}}=\dfrac{\omega_2-\omega_1}{k_2-k_1}=\dfrac{8\omega}{2k}=\dfrac{4\omega}{k}$.

EVALUATE: The two expressions agree.

40.4. IDENTIFY: Apply the Heisenberg uncertainty principle in the form $\Delta x\Delta p_x\ge\hbar/2$.

SET UP: The uncertainty in the particle position is proportional to the width of $\psi(x)$.

EXECUTE: **(a)** The width of $\psi(x)$ is inversely proportional to $\sqrt{\alpha}$. This can be seen by either plotting the function for different values of α or by finding the full width at half-maximum. The particle's uncertainty in position decreases with increasing α.

(b) Since the uncertainty in position decreases, the uncertainty in momentum must increase.
EVALUATE: As α increases, the function $A(k)$ in Eq. (40.19) must become broader.

40.5. **IDENTIFY** and **SET UP:** $\psi(x) = A\sin kx.$ The position probability density is given by $|\psi(x)|^2 = A^2 \sin^2 kx.$

EXECUTE: **(a)** The probability is highest where $\sin kx = 1$ so $kx = 2\pi x/\lambda = n\pi/2,\ n = 1, 3, 5, \ldots$
$x = n\lambda/4,\ n = 1, 3, 5, \ldots$ so $x = \lambda/4, 3\lambda/4, 5\lambda/4, \ldots$

(b) The probability of finding the particle is zero where $|\psi|^2 = 0,$ which occurs where $\sin kx = 0$ and $kx = 2\pi x/\lambda = n\pi,\ n = 0, 1, 2, \ldots$
$x = n\lambda/2,\ n = 0, 1, 2, \ldots,$ so $x = 0, \lambda/2, \lambda, 3\lambda/2, \ldots$

EVALUATE: The situation is analogous to a standing wave, with the probability analogous to the square of the amplitude of the standing wave.

40.6. **IDENTIFY:** Determine whether or not $-\dfrac{\hbar^2}{2m}\dfrac{d^2\psi}{dx^2} + U\psi$ is equal to $E\psi,$ for some value of E.

SET UP: $-\dfrac{\hbar^2}{2m}\dfrac{d^2\psi_1}{dx^2} + U\psi_1 = E_1\psi_1$ and $-\dfrac{\hbar^2}{2m}\dfrac{d^2\psi_2}{dx^2} + U\psi_2 = E_2\psi_2.$

EXECUTE: $-\dfrac{\hbar^2}{2m}\dfrac{d^2\psi}{dx^2} + U\psi = BE_1\psi_1 + CE_2\psi_2.$ If ψ were a solution with energy E, then $BE_1\psi_1 + CE_2\psi_2 = BE\psi_1 + CE\psi_2$ or $B(E_1 - E)\psi_1 = C(E - E_2)\psi_2.$ This would mean that ψ_1 is a constant multiple of ψ_2, and ψ_1 and ψ_2 would be wave functions with the same energy. However, $E_1 \neq E_2,$ so this is not possible, and ψ cannot be a solution to the equation $-\dfrac{\hbar^2}{2m}\dfrac{d^2\psi}{dx^2} + U\psi = E\psi.$

EVALUATE: ψ is a solution if $E_1 = E_2$.

40.7. **IDENTIFY:** We are dealing with a particle in a box.

SET UP: $E = hc/\lambda,\ E_n = n^2\dfrac{\pi^2\hbar^2}{2mL^2}.$ We want the wavelength.

EXECUTE: The longest wavelength (lowest energy) photon is from a transition between the $n = 1$ to $n = 2$ states. The energy of this photon is equal to the energy difference between these states.

$$\Delta E_1 = \frac{\pi^2\hbar^2}{2mL^2}\left(2^2 - 1^2\right) = \frac{hc}{\lambda_1}.$$

The next longest wavelength photon is from a transition from the $n = 1$ to the $n = 3$ state.

$$\Delta E_2 = \frac{\pi^2\hbar^2}{2mL^2}\left(3^2 - 1^2\right) = \frac{hc}{\lambda_2}.$$

Dividing these two equations and solving for λ_2 gives

$$\frac{4-1}{9-1} = \frac{\lambda_2}{\lambda_1}.\ \lambda_2 = \frac{3}{8}\lambda_1 = \frac{3}{8}(420\text{ nm}) = 158\text{ nm}.$$

EVALUATE: The next longest photon (starting from the ground state) would be between the $n = 1$ and $n = 4$ states.

40.8. **IDENTIFY:** To describe a real situation, a wave function must be normalizable.

SET UP: $|\psi|^2\,dV$ is the probability that the particle is found in volume dV. Since the particle must be *somewhere*, ψ must have the property that $\int|\psi|^2 dV = 1$ when the integral is taken over all space.

EXECUTE: **(a)** For normalization of the one-dimensional wave function, we have

$$1=\int_{-\infty}^{\infty}|\psi|^2dx=\int_{-\infty}^{0}(Ae^{bx})^2dx+\int_0^{\infty}(Ae^{-bx})^2dx=\int_{-\infty}^{0}A^2e^{2bx}dx+\int_0^{\infty}A^2e^{-2bx}dx.$$

$$1=A^2\left\{\frac{e^{2bx}}{2b}\bigg|_{-\infty}^{0}+\frac{e^{-2bx}}{-2b}\bigg|_{0}^{\infty}\right\}=\frac{A^2}{b},\text{ which gives } A=\sqrt{b}=\sqrt{2.00\text{ m}^{-1}}=1.41\text{ m}^{-1/2}.$$

(b) The graph of the wavefunction versus x is given in Figure 40.8.

(c) (i) $P=\int_{-0.500\text{ m}}^{+0.500\text{ m}}|\psi|^2dx=2\int_0^{+0.500\text{ m}}A^2e^{-2bx}dx,$ where we have used the fact that the wave function is an even function of x. Evaluating the integral gives

$$P=\frac{-A^2}{b}(e^{-2b(0.500\text{ m})}-1)=\frac{-(2.00\text{ m}^{-1})}{2.00\text{ m}^{-1}}(e^{-2.00}-1)=0.865.$$

There is a little more than an 86% probability that the particle will be found within 50 cm of the origin.

(ii) $P=\int_{-\infty}^{0}(Ae^{bx})^2dx=\int_{-\infty}^{0}A^2e^{2bx}dx=\frac{A^2}{2b}=\frac{2.00\text{ m}^{-1}}{2(2.00\text{ m}^{-1})}=\frac{1}{2}=0.500.$

There is a 50-50 chance that the particle will be found to the left of the origin, which agrees with the fact that the wave function is symmetric about the y-axis.

(iii) $P=\int_{0.500\text{ m}}^{1.00\text{ m}}A^2e^{-2bx}dx=\frac{A^2}{-2b}(e^{-2(2.00\text{ m}^{-1})(1.00\text{ m})}-e^{-2(2.00\text{ m}^{-1})(0.500\text{ m})})=-\frac{1}{2}(e^{-4}-e^{-2})$

$=0.0585.$

EVALUATE: There is little chance of finding the particle in regions where the wave function is small.

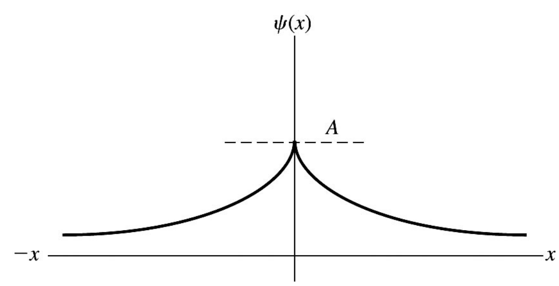

Figure 40.8

40.9. **IDENTIFY** and **SET UP:** The energy levels for a particle in a box are given by $E_n=\frac{n^2h^2}{8mL^2}.$

EXECUTE: **(a)** The lowest level is for $n=1,$ and $E_1=\frac{(1)(6.626\times10^{-34}\text{ J}\cdot\text{s})^2}{8(0.20\text{ kg})(1.3\text{ m})^2}=1.6\times10^{-67}\text{ J}.$

(b) $E=\frac{1}{2}mv^2,$ so $v=\sqrt{\frac{2E}{m}}=\sqrt{\frac{2(1.2\times10^{-67}\text{ J})}{0.20\text{ kg}}}=1.3\times10^{-33}\text{ m/s}.$ If the ball has this speed the time it would take it to travel from one side of the table to the other is

$$t=\frac{1.3\text{ m}}{1.3\times10^{-33}\text{ m/s}}=1.0\times10^{33}\text{ s}.$$

(c) $E_1=\frac{h^2}{8mL^2},\ E_2=4E_1,$ so $\Delta E=E_2-E_1=3E_1=3(1.6\times10^{-67}\text{ J})=4.9\times10^{-67}\text{ J}.$

EVALUATE: **(d)** No, quantum mechanical effects are not important for the game of billiards. The discrete, quantized nature of the energy levels is completely unobservable.

40.10. **IDENTIFY:** Solve the energy-level equation $E_n = \dfrac{n^2h^2}{8mL^2}$ for L.

SET UP: The ground state has $n = 1$.

EXECUTE: $L = \dfrac{h}{\sqrt{8mE_1}} = \dfrac{(6.626\times10^{-34}\ \text{J}\cdot\text{s})}{\sqrt{8(1.673\times10^{-27}\ \text{kg})(5.0\times10^{6}\ \text{eV})(1.602\times10^{-19}\ \text{J/eV})}} = 6.4\times10^{-15}\ \text{m}$

EVALUATE: The value of L we calculated is on the order of the diameter of a nucleus.

40.11. **IDENTIFY:** An electron in the lowest energy state in this box must have the same energy as it would in the ground state of hydrogen.

SET UP: The energy of the n^{th} level of an electron in a box is $E_n = \dfrac{nh^2}{8mL^2}$.

EXECUTE: An electron in the ground state of hydrogen has an energy of $-13.6\ \text{eV}$, so find the width corresponding to an energy of $E_1 = 13.6\ \text{eV}$. Solving for L gives

$$L = \frac{h}{\sqrt{8mE_1}} = \frac{(6.626\times10^{-34}\ \text{J}\cdot\text{s})}{\sqrt{8(9.11\times10^{-31}\ \text{kg})(13.6\ \text{eV})(1.602\times10^{-19}\ \text{J/eV})}} = 1.66\times10^{-10}\ \text{m}.$$

EVALUATE: This width is of the same order of magnitude as the diameter of a Bohr atom with the electron in the K shell.

40.12. **IDENTIFY and SET UP:** The energy of a photon is $E = hf = h\dfrac{c}{\lambda}$. The energy levels of a particle in a box are given by $E_n = \dfrac{nh^2}{8mL^2}$.

EXECUTE: **(a)** $E = (6.63\times10^{-34}\ \text{J}\cdot\text{s})\dfrac{(3.00\times10^{8}\ \text{m/s})}{(122\times10^{-9}\ \text{m})} = 1.63\times10^{-18}\ \text{J}$. $\Delta E = \dfrac{h^2}{8mL^2}(n_1^2 - n_2^2)$.

$$L = \sqrt{\frac{h^2(n_1^2 - n_2^2)}{8m\Delta E}} = \sqrt{\frac{(6.63\times10^{-34}\ \text{J}\cdot\text{s})^2(2^2-1^2)}{8(9.11\times10^{-31}\ \text{kg})(1.63\times10^{-18}\ \text{J})}} = 3.33\times10^{-10}\ \text{m}.$$

(b) The ground state energy for an electron in a box of the calculated dimensions is

$E = \dfrac{h^2}{8mL^2} = \dfrac{(6.63\times10^{-34}\ \text{J}\cdot\text{s})^2}{8(9.11\times10^{-31}\ \text{kg})(3.33\times10^{-10}\ \text{m})^2} = 5.43\times10^{-19}\ \text{J} = 3.40\ \text{eV}$ (one-third of the original photon energy), which does not correspond to the $-13.6\ \text{eV}$ ground state energy of the hydrogen atom.

EVALUATE: **(c)** Note that the energy levels for a particle in a box are proportional to n^2, whereas the energy levels for the hydrogen atom are proportional to $-\dfrac{1}{n^2}$. A one-dimensional box is not a good model for a hydrogen atom.

40.13. **IDENTIFY and SET UP:** The equation $E_n = \dfrac{n^2h^2}{8mL^2}$ gives the energy levels. Use this to obtain an expression for $E_2 - E_1$ and use the value given for this energy difference to solve for L.

EXECUTE: Ground state energy is $E_1 = \dfrac{h^2}{8mL^2}$; first excited state energy is $E_2 = \dfrac{4h^2}{8mL^2}$. The energy separation between these two levels is $\Delta E = E_2 - E_1 = \dfrac{3h^2}{8mL^2}$. This gives

$$L = h\sqrt{\frac{3}{8m\Delta E}} = L = 6.626\times10^{-34}\ \text{J}\cdot\text{s}\sqrt{\frac{3}{8(9.109\times10^{-31}\ \text{kg})(3.0\ \text{eV})(1.602\times10^{-19}\ \text{J/1 eV})}}$$

$= 6.1\times10^{-10}\ \text{m} = 0.61\ \text{nm}$.

EVALUATE: This energy difference is typical for an atom and L is comparable to the size of an atom.

40.14. **IDENTIFY:** The energy of the absorbed photon must be equal to the energy difference between the two states.

SET UP and **EXECUTE:** The second excited state energy is $E_3 = \dfrac{9\pi^2\hbar^2}{2mL^2}$. The ground state energy is $E_1 = \dfrac{\pi^2\hbar^2}{2mL^2}$. $E_1 = 2.00$ eV, so $E_3 = 18.0$ eV. For the transition $\Delta E = \dfrac{4\pi^2\hbar^2}{mL^2}$. $\dfrac{hc}{\lambda} = \Delta E$.

$$\lambda = \frac{hc}{\Delta E} = \frac{(4.136\times10^{-15}\text{ eV}\cdot\text{s})(2.998\times10^{8}\text{ m/s})}{16.0\text{ eV}} = 7.75\times10^{-8}\text{ m} = 77.5\text{ nm}.$$

EVALUATE: This wavelength is much shorter than those of visible light.

40.15. **IDENTIFY:** We are dealing with a particle in a box and the de Broglie wavelength.

SET UP: $\lambda = h/p$, $E_n = n^2\dfrac{\pi^2\hbar^2}{2mL^2}$, $K = p^2/2m$.

EXECUTE: **(a)** We want the momentum. From the 9 in the numerator of the given energy, we see that $n^2 = 9$, so $n = 3$. The particle's energy is kinetic energy, so $E_3 = K_3 = p_3^2/2m$. Therefore,

$$E_3 = \frac{9\pi^2\hbar^2}{2mL^2} = \frac{p_3^2}{2m}.\ p = \sqrt{\frac{9\pi^2\hbar^2}{L^2}} = \frac{3h}{2L}.$$

(b) We want L/λ. $L/\lambda = L/(h/p) = Lp/h = L(3h/2L)/h = 3/2$.

EVALUATE: The ration in part (b) would be different if the particle were in a different state.

40.16. **IDENTIFY:** Find x where ψ_1 is zero and where it is a maximum.

SET UP: $\psi_1 = \sqrt{\dfrac{2}{L}}\sin\left(\dfrac{\pi x}{L}\right)$.

EXECUTE: **(a)** The wave function for $n = 1$ vanishes only at $x = 0$ and $x = L$ in the range $0 \le x \le L$.
(b) In the range for x, the sine term is a maximum only at the middle of the box, $x = L/2$.

EVALUATE: **(c)** The answers to parts (a) and (b) are consistent with the figure.

40.17. **IDENTIFY:** We are dealing with a particle in a box.

SET UP: $E_n = n^2\dfrac{\pi^2\hbar^2}{2mL^2}$, $m_A = 9m_B, L_B = 2L_A, E_A = E_B$. We want the lowest possible quantum numbers n_A and n_B of the two states.

EXECUTE: Equate the energies and determine the lowest possible values of n_A and n_B.

$$\frac{n_A^2\pi^2\hbar^2}{2m_A^2L_A^2} = \frac{n_B^2\pi^2\hbar^2}{2m_B^2L_B^2}.\quad \frac{n_A^2}{(9m_B)(L_B/2)^2} = \frac{n_B^2}{m_BL_B^2}.\ 4n_A^2 = 9n_B^2.$$

If $n_B = 2$, then $n_A = 3$, so the lowest possible values of the quantum numbers are $n_A = 3$, $n_B = 2$.

EVALUATE: Other states exist, such as $n_A = 6$, $n_B = 4$, but these are the lowest ones.

40.18. **IDENTIFY:** The energy levels are given by $E_n = \dfrac{n^2h^2}{8mL^2}$. The wavelength λ of the photon absorbed in an atomic transition is related to the transition energy ΔE by $\lambda = \dfrac{hc}{\Delta E}$.

SET UP: For the ground state $n = 1$ and for the third excited state $n = 4$.
EXECUTE: **(a)** The third excited state is $n = 4$, so

$$\Delta E = (4^2 - 1)\frac{h^2}{8mL^2} = \frac{15(6.626\times10^{-34}\text{ J}\cdot\text{s})^2}{8(9.11\times10^{-31}\text{ kg})(0.360\times10^{-9}\text{ m})^2} = 6.973\times10^{-18}\text{ J} = 43.5\text{ eV}.$$

(b) $\lambda = \dfrac{hc}{\Delta E} = \dfrac{(6.63\times10^{-34}\ \text{J}\cdot\text{s})(3.0\times10^{8}\ \text{m/s})}{6.973\times10^{-18}\ \text{J}} = 28.5\ \text{nm}.$

EVALUATE: This photon is an x ray. As the width of the box increases the transition energy for this transition decreases and the wavelength of the photon increases.

40.19. **IDENTIFY** and **SET UP:** $\lambda = \dfrac{h}{p} = \dfrac{h}{\sqrt{2mE}}$. The energy of the electron in level n is given by the equation $E_n = \dfrac{n^2h^2}{8mL^2}$.

EXECUTE: **(a)** $E_1 = \dfrac{h^2}{8mL^2} \Rightarrow \lambda_1 = \dfrac{h}{\sqrt{2mh^2/8mL^2}} = 2L = 2(3.0\times10^{-10}\ \text{m}) = 6.0\times10^{-10}\ \text{m}.$ The wavelength is twice the width of the box. $p_1 = \dfrac{h}{\lambda_1} = \dfrac{(6.63\times10^{-34}\ \text{J}\cdot\text{s})}{6.0\times10^{-10}\ \text{m}} = 1.1\times10^{-24}\ \text{kg}\cdot\text{m/s}.$

(b) $E_2 = \dfrac{4h^2}{8mL^2} \Rightarrow \lambda_2 = L = 3.0\times10^{-10}\ \text{m}.$ The wavelength is the same as the width of the box.

$p_2 = \dfrac{h}{\lambda_2} = 2p_1 = 2.2\times10^{-24}\ \text{kg}\cdot\text{m/s}.$

(c) $E_3 = \dfrac{9h^2}{8mL^2} \Rightarrow \lambda_3 = \dfrac{2}{3}L = 2.0\times10^{-10}\ \text{m}.$ The wavelength is two-thirds the width of the box.

$p_3 = 3p_1 = 3.3\times10^{-24}\ \text{kg}\cdot\text{m/s}.$

EVALUATE: In each case the wavelength is an integer multiple of $\lambda/2$. In the n^{th} state, $p_n = np_1$.

40.20. **IDENTIFY:** The energy of the photon is equal to the energy difference ΔE between the energy levels of the electron.

SET UP: The energy levels of an electron in a one-dimensional box are $E_n = \dfrac{n^2h^2}{8mL^2}$. The energy of the absorbed photon is $\Delta E = \dfrac{hc}{\lambda}$.

EXECUTE: **(a)** $\Delta E_{1\to2} = (h^2/8mL^2)(2^2 - 1^2) = 3(h^2/8mL^2) = hc/\lambda_{1\to2}.$

$\Delta E_{2\to3} = (h^2/8mL^2)(3^2 - 2^2) = 5(h^2/8mL^2) = hc/\lambda_{2\to3}.$ Take ratios of these two equations, giving

$\dfrac{3}{5} = \dfrac{hc/\lambda_{1\to2}}{hc/\lambda_{2\to3}} = \dfrac{\lambda_{2\to3}}{\lambda_{1\to2}} \ \rightarrow\ \lambda_{2\to3} = (3/5)\lambda_{1\to2} = (3/5)(426\ \text{nm}) = 256\ \text{nm}.$

(b) Follow the same procedure as in part (a), giving

$$\lambda_{1\to3} = (3/8)\lambda_{1\to2} = (3/8)(426\ \text{nm}) = 160\ \text{nm}.$$

(c) From part (a), we know that $\Delta E_{1\to2} = \dfrac{3h^2}{8mL^2} = \dfrac{hc}{\lambda_{1\to2}}$. Solving for L gives

$$L = \sqrt{\frac{3h\lambda_{1\to2}}{8\,mc}} = \sqrt{\frac{3(6.626\times10^{-34}\ \text{J}\cdot\text{s})(426\times10^{-9}\ \text{m})}{8(9.109\times10^{-31}\ \text{kg})(2.998\times10^{8}\ \text{m/s})}} = 6.23\times10^{-10}\ \text{m} = 0.623\ \text{nm}.$$

EVALUATE: The width L of this box is about 6 times the diameter of a hydrogen atom.

40.21. **IDENTIFY:** We are dealing with a particle in a box.

SET UP: $-\dfrac{\hbar^2}{2m}\dfrac{d^2\psi}{dx} = E\psi.$

EXECUTE: **(a)** $\psi_n = A\cos k_n x.$ Take the second derivative and use it to find E_n as follows.

$$-\frac{\hbar^2}{2m}\left(-Ak_n^2 \cos k_n x\right) = EA\cos k_n x. \;\; E_n = \frac{\hbar^2}{2m}k_n^2.$$

The wave function must be zero at $x = \pm L/2$. This gives

$A\cos[k_n(\pm L/2)] = 0.\; k_n(L/2) = \pi/2, 3\pi/2, 5\pi/2, \cdots .k_n = n\pi/L,\; n = 1,3,5,\cdots$

(b) $\psi_n = A\sin k_n x.$ Follow the same procedure as in part (a) to obtain $k_n = n\pi/L,\; n = 2, 4, 6, \ldots$

(c) We want the allowed energies.

$\psi_n = A\sin k_n x$: Combine the results for E_n and k_n from part (b) to obtain E_n.

$$E_n = \frac{\hbar^2}{2m}\left(\frac{n\pi}{L}\right)^2 = \frac{\hbar^2\pi^2}{2mL^2}n^2,\; n = 2,4,6,\cdots$$

$\psi_n = A\cos k_n x$: Follow the same procedure using the results from part (a), which gives

$$E_n = \frac{\hbar^2\pi^2}{2mL^2}n^2,\; n = 1,3,5,\cdots$$

EVALUATE: **(d)** The set of energies found here is the *same* as those in Eq. (40.31). This result occurs because the physical system (i.e., the box) does not "know" where we placed the origin of coordinates, so its behavior should be the same in either case.

40.22. **IDENTIFY:** $\lambda = \frac{h}{p}$. p is related to E by $E = \frac{p^2}{2m} + U.$

SET UP: For $x > L,\; U = U_0.$ For $0 < x < L,\; U = 0.$

EXECUTE: For $0 < x < L,\;\; p = \sqrt{2mE} = \sqrt{2m(3U_0)}$ and $\lambda_{\text{in}} = \frac{h}{\sqrt{2m(3U_0)}}$. For $x > L,$

$p = \sqrt{2m(E - U_0)} = \sqrt{2m(2U_0)}$ and $\lambda_{\text{out}} = \frac{h}{\sqrt{2m(E-U_0)}} = \frac{h}{\sqrt{2m(2U_0)}}$. Thus, the ratio of the wavelengths is $\frac{\lambda_{\text{out}}}{\lambda_{\text{in}}} = \frac{\sqrt{2m(3U_0)}}{\sqrt{2m(2U_0)}} = \sqrt{\frac{3}{2}}.$

EVALUATE: For $x > L$ some of the energy is potential and the kinetic energy is less than it is for $0 < x < L,$ where $U = 0.$ Therefore, outside the box p is less and λ is greater than inside the box.

40.23. **IDENTIFY:** Figure 40.15b in the textbook gives values for the bound state energy of a square well for which $U_0 = 6E_{\text{1-IDW}}$.

SET UP: $E_{\text{1-IDW}} = \frac{\pi^2\hbar^2}{2mL^2}.$

EXECUTE: $E_1 = 0.625E_{\text{1-IDW}} = 0.625\frac{\pi^2\hbar^2}{2mL^2};\; E_1 = 2.00\text{ eV} = 3.20\times10^{-19}\text{ J}.$

$$L = \pi\hbar\left(\frac{0.625}{2(9.109\times10^{-31}\text{ kg})(3.20\times10^{-19}\text{ J})}\right)^{1/2} = 3.43\times10^{-10}\text{ m}.$$

EVALUATE: As L increases the ground state energy decreases.

40.24. **IDENTIFY:** In a finite potential well, the energy levels are lowered compared to the energy levels in an infinite well. The energy of the photon removes the electron from its energy state in the well and any left-over energy is the kinetic energy K of the electron.

SET UP: The energy levels for an infinitely deep well are $E_{n-\text{IDW}} = \frac{n^2h^2}{8mL^2}$, and $n = 1$ is the ground state. The energy of a photon is $E = hc/\lambda.$

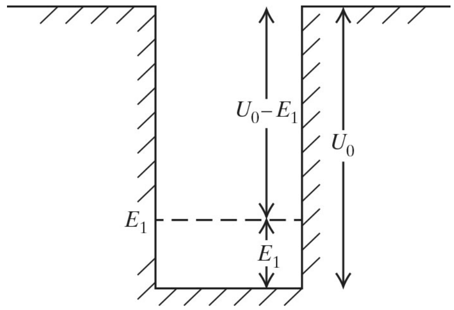

Figure 40.24

EXECUTE: Figure 40.24 illustrates the various energies involved. In this case, $U_0 = 6E_{1\text{-IDW}}$. Figure 40.15b in the textbook shows that the ground state energy E_1 in the finite well is $E_1 = 0.625E_{1\text{-IDW}}$.

The electron already has energy E_1 in the well, so the energy just to remove it from the well is $U_0 - E_1$.

Conservation of energy gives $E_{\text{photon}} = E_{\text{remove el}} + K$, which we can write as

$$\frac{hc}{\lambda} = (U_0 - E_1) + K = 6E_{1-\text{IDW}} - 0.625E_{1-\text{IDW}} + K = 5.375E_{1-\text{IDW}} + K.$$

Solving for K and using $E_{1-\text{IDW}} = \dfrac{h^2}{8mL^2}$ gives

$$K = \frac{hc}{\lambda} - 5.375E_{1-\text{IDW}} = \frac{hc}{\lambda} - \frac{5.735h^2}{8mL^2}.$$

Using $\lambda = 72 \times 10^{-9}$ m and $L = 4.00 \times 10^{-10}$ m, plus the usual values of the constants h, c, and m, we get $K = 2.76 \times 10^{-18}$ J – 2.02×10^{-18} J = 7.4×10^{-19} J, which we can express in electron-volts as K = 17.2 eV – 12.6 eV = 4.6 eV.

EVALUATE: The photon has 17.2 eV and it takes 12.6 eV just to remove the electron from the well, so the remaining 4.6 eV is the kinetic energy of the electron.

40.25. **IDENTIFY:** The energy of the photon is the energy given to the electron.

SET UP: Since $U_0 = 6E_{1\text{-IDW}}$ we can use the result $E_1 = 0.625E_{1\text{-IDW}}$ from Section 40.4. When the electron is outside the well it has potential energy U_0, so the minimum energy that must be given to the electron is $U_0 - E_1 = 5.375E_{1\text{-IDW}}$.

EXECUTE: The maximum wavelength of the photon would be

$$\lambda = \frac{hc}{U_0 - E_1} = \frac{hc}{(5.375)(h^2/8mL^2)} = \frac{8mL^2c}{(5.375)h} = \frac{8(9.11\times10^{-31}\text{ kg})(1.50\times10^{-9}\text{ m})^2(3.00\times10^{8}\text{ m/s})}{(5.375)(6.63\times10^{-34}\text{ J}\cdot\text{s})}$$
$$= 1.38\times10^{-6}\text{ m}.$$

EVALUATE: This photon is in the infrared. The wavelength of the photon decreases when the width of the well decreases.

40.26. **IDENTIFY:** The longest wavelength corresponds to the smallest energy change.

SET UP: The ground level energy level of the infinite well is $E_{1\text{-IDW}} = \dfrac{h^2}{8mL^2}$, and the energy of the photon must be equal to the energy difference between the two levels.

EXECUTE: The 582-nm photon must correspond to the $n=1$ to $n=2$ transition. Since $U_0 = 6E_{\text{1-IDW}}$, we have $E_2 = 2.43E_{\text{1-IDW}}$ and $E_1 = 0.625E_{\text{1-IDW}}$. The energy of the photon is equal to the energy difference between the two levels, and $E_{\text{1-IDW}} = \dfrac{h^2}{8mL^2}$, which gives

$E_\gamma = E_2 - E_1 \Rightarrow \dfrac{hc}{\lambda} = (2.43-0.625)E_{\text{1-IDW}} = \dfrac{1.805\,h^2}{8mL^2}$. Solving for L gives

$$L = \sqrt{\frac{(1.805)h\lambda}{8mc}} = \sqrt{\frac{(1.805)(6.626\times10^{-34}\ \text{J}\cdot\text{s})(5.82\times10^{-7}\ \text{m})}{8(9.11\times10^{-31}\ \text{kg})(3.00\times10^{8}\ \text{m/s})}} = 5.64\times10^{-10}\ \text{m} = 0.564\ \text{nm}.$$

EVALUATE: This width is slightly more than half that of a Bohr hydrogen atom.

40.27. IDENTIFY: Find the transition energy ΔE and set it equal to the energy of the absorbed photon. Use $E = hc/\lambda$, to find the wavelength of the photon.

SET UP: $U_0 = 6E_{\text{1-IDW}}$, as in Figure 40.15 in the textbook, so $E_1 = 0.625E_{\text{1-IDW}}$ and $E_3 = 5.09E_{\text{1-IDW}}$ with $E_{\text{1-IDW}} = \dfrac{\pi^2\hbar^2}{2mL^2}$. In this problem the particle bound in the well is a proton, so $m = 1.673\times10^{-27}$ kg.

EXECUTE: $E_{\text{1-IDW}} = \dfrac{\pi^2\hbar^2}{2mL^2} = \dfrac{\pi^2(1.055\times10^{-34}\ \text{J}\cdot\text{s})^2}{2(1.673\times10^{-27}\ \text{kg})(4.0\times10^{-15}\ \text{m})^2} = 2.052\times10^{-12}$ J. The transition energy is $\Delta E = E_3 - E_1 = (5.09-0.625)E_{\text{1-IDW}} = 4.465E_{\text{1-IDW}}$. $\Delta E = 4.465(2.052\times10^{-12}\ \text{J}) = 9.162\times10^{-12}$ J. The wavelength of the photon that is absorbed is related to the transition energy by $\Delta E = hc/\lambda$, so

$$\lambda = \frac{hc}{\Delta E} = \frac{(6.626\times10^{-34}\ \text{J}\cdot\text{s})(2.998\times10^{8}\ \text{m/s})}{9.162\times10^{-12}\ \text{J}} = 2.2\times10^{-14}\ \text{m} = 22\ \text{fm}.$$

EVALUATE: The wavelength of the photon is comparable to the size of the well.

40.28. IDENTIFY: The tunneling probability is $T = Ge^{-2\kappa L}$, with $G = 16\dfrac{E}{U_0}\left(1-\dfrac{E}{U_0}\right)$ and $\kappa = \dfrac{\sqrt{2m(U_0-E)}}{\hbar}$.

So $T = 16\dfrac{E}{U_0}\left(1-\dfrac{E}{U_0}\right)e^{\frac{-2\sqrt{2m(U_0-E)}}{\hbar}L}$.

SET UP: $U_0 = 30.0\times10^6$ eV, $L = 2.0\times10^{-15}$ m, $m = 6.64\times10^{-27}$ kg.

EXECUTE: **(a)** $U_0 - E = 1.0\times10^6$ eV $(E = 29.0\times10^6\ \text{eV})$, $T = 0.090$.

(b) If $U_0 - E = 10.0\times10^6$ eV $(E = 20.0\times10^6\ \text{eV})$, $T = 0.014$.

EVALUATE: T is less when $U_0 - E$ is 10.0 MeV than when $U_0 - E$ is 1.0 MeV.

40.29. IDENTIFY and SET UP: The probability is $T = Ge^{-2\kappa L}$, with $G = 16\dfrac{E}{U_0}\left(1-\dfrac{E}{U_0}\right)$ and $\kappa = \dfrac{\sqrt{2m(U_0-E)}}{\hbar}$. $E = 32$ eV, $U_0 = 41$ eV, $L = 0.25\times10^{-9}$ m. Calculate T.

EXECUTE: **(a)** $G = 16\dfrac{E}{U_0}\left(1-\dfrac{E}{U_0}\right) = 16\dfrac{32}{41}\left(1-\dfrac{32}{41}\right) = 2.741.$

$$\kappa = \frac{\sqrt{2m(U_0-E)}}{\hbar}.$$

$$\kappa = \frac{\sqrt{2(9.109\times10^{-31}\ \text{kg})(41\ \text{eV}-32\ \text{eV})(1.602\times10^{-19}\ \text{J/eV})}}{1.055\times10^{-34}\ \text{J}\cdot\text{s}} = 1.536\times10^{10}\ \text{m}^{-1}.$$

$$T = Ge^{-2\kappa L} = (2.741)e^{-2(1.536\times10^{10}\ \text{m}^{-1})(0.25\times10^{-9}\ \text{m})} = 2.741e^{-7.68} = 0.0013.$$

(b) The only change is the mass m, which appears in κ.

$$\kappa = \frac{\sqrt{2m(U_0 - E)}}{\hbar}.$$

$$\kappa = \frac{\sqrt{2(1.673\times10^{-27}\ \text{kg})(41\ \text{eV} - 32\ \text{eV})(1.602\times10^{-19}\ \text{J/eV})}}{1.055\times10^{-34}\ \text{J}\cdot\text{s}} = 6.584\times10^{11}\ \text{m}^{-1}.$$

Then $T = Ge^{-2\kappa L} = (2.741)e^{-2(6.584\times10^{11}\ \text{m}^{-1})(0.25\times10^{-9}\ \text{m})} = 2.741e^{-392.2} = 10^{-143}$.

EVALUATE: The more massive proton has a much smaller probability of tunneling than the electron does.

40.30. IDENTIFY: The transmission coefficient is $T = 16\frac{E}{U_0}\left(1 - \frac{E}{U_0}\right)e^{-2\sqrt{2m(U_0-E)}L/\hbar}$.

SET UP: $E = 5.0$ eV, $L = 0.60\times10^{-9}$ m, and $m = 9.11\times10^{-31}$ kg.

EXECUTE: **(a)** $U_0 = 7.0\ \text{eV} \Rightarrow T = 5.5\times10^{-4}$.

(b) $U_0 = 9.0\ \text{eV} \Rightarrow T = 1.8\times10^{-5}$.

(c) $U_0 = 13.0\ \text{eV} \Rightarrow T = 1.1\times10^{-7}$.

EVALUATE: T decreases when the height of the barrier increases.

40.31. IDENTIFY: The tunneling probability is $T = 16\frac{E}{U_0}\left(1 - \frac{E}{U_0}\right)e^{-2L\sqrt{2m(U_0-E)}/\hbar}$.

SET UP: $\frac{E}{U_0} = \frac{6.0\ \text{eV}}{11.0\ \text{eV}}$ and $E - U_0 = 5\ \text{eV} = 8.0\times10^{-19}$ J.

EXECUTE: **(a)** $L = 0.80\times10^{-9}$ m:

$$T = 16\left(\frac{6.0\ \text{eV}}{11.0\ \text{eV}}\right)\left(1 - \frac{6.0\ \text{ev}}{11.0\ \text{eV}}\right)e^{-2(0.80\times10^{-9}\ \text{m})\sqrt{2(9.11\times10^{-31}\ \text{kg})(8.0\times10^{-19}\ \text{J})}/1.055\times10^{-34}\ \text{J}\cdot\text{s}} = 4.4\times10^{-8}.$$

(b) $L = 0.40\times10^{-9}$ m: $T = 4.2\times10^{-4}$.

EVALUATE: The tunneling probability is less when the barrier is wider.

40.32. IDENTIFY and **SET UP:** Use $\lambda = h/p$, where $K = p^2/2m$ and $E = K + U$.

EXECUTE: $\lambda = h/p = h/\sqrt{2mK}$, so $\lambda\sqrt{K}$ is constant. $\lambda_1\sqrt{K_1} = \lambda_2\sqrt{K_2}$; λ_1 and K_1 are for $x > L$ where $K_1 = 2U_0$ and λ_2 and K_2 are for $0 < x < L$ where $K_2 = E - U_0 = U_0$.

$$\frac{\lambda_1}{\lambda_2} = \sqrt{\frac{K_2}{K_1}} = \sqrt{\frac{U_0}{2U_0}} = \frac{1}{\sqrt{2}}.$$

EVALUATE: When the particle is passing over the barrier its kinetic energy is less and its wavelength is larger.

40.33. IDENTIFY and **SET UP:** The energy levels are given by $E_n = (n + \frac{1}{2})\hbar\omega$, where $\omega = \sqrt{\frac{k'}{m}}$.

EXECUTE: $\omega = \sqrt{\frac{k'}{m}} = \sqrt{\frac{110\ \text{N/m}}{0.250\ \text{kg}}} = 21.0$ rad/s.

The ground state energy is given by $E_n = (n + \frac{1}{2})\hbar\omega$, where $n = 0$.

$E_0 = \frac{1}{2}\hbar\omega = \frac{1}{2}(1.055\times10^{-34}\ \text{J}\cdot\text{s})(21.0\ \text{rad/s}) = 1.11\times10^{-33}\ \text{J}(1\ \text{eV}/1.602\times10^{-19}\ \text{J}) = 6.93\times10^{-15}$ eV.

$E_n = (n + \frac{1}{2})\hbar\omega$, $E_{(n+1)} = (n + 1 + \frac{1}{2})\hbar\omega$.

The energy separation between these adjacent levels is

$$\Delta E = E_{n+1} - E_n = \hbar\omega = 2E_0 = 2(1.11\times10^{-33}\text{ J}) = 2.22\times10^{-33}\text{ J} = 1.39\times10^{-14}\text{ eV}.$$

EVALUATE: These energies are extremely small; quantum effects are not important for this oscillator.

40.34. IDENTIFY: This problem is about a quantum harmonic oscillator and the uncertainty principle.

SET UP: $K = p^2/2m$, $p_{\max} = mv_{\max}$, $E_n = \left(n+\frac{1}{2}\right)\hbar\sqrt{\frac{k'}{m}} = \left(n+\frac{1}{2}\right)\hbar\omega.$

EXECUTE: **(a)** We want $p_{\max}$. When $v = v_{\max}$, $x = 0$, so $K_{\max} = E_n$. Using $K = p^2/2m$ gives

$$\frac{p_{\max}^2}{2m} = \left(n+\frac{1}{2}\right)\hbar\sqrt{\frac{k'}{m}}.\quad p_{\max} = \sqrt{(2n+1)\hbar\sqrt{k'm}}.$$

(b) We want the amplitude A. When $x = A$, $v = 0$, so $\frac{1}{2}k'A^2 = E_n$. Use this fact and solve for A.

$$\frac{1}{2}k'A^2 = \left(n+\frac{1}{2}\right)\hbar\sqrt{\frac{k'}{m}}.\ A = \sqrt{\frac{(2n+1)\hbar}{\sqrt{k'm}}}.$$

(c) We want $\Delta x\Delta p_x$. Use the uncertainties given in the problem and the results of (a) and (b).

$$\Delta x\Delta p_x = \frac{A}{\sqrt{2}}\frac{p_{\max}}{\sqrt{2}} = \frac{1}{2}\sqrt{\frac{(2n+1)\hbar}{\sqrt{k'm}}}\sqrt{(2n+1)\hbar\sqrt{k'm}} = \left(n+\frac{1}{2}\right)\hbar.$$

As n increases, the uncertainty product also increases.

EVALUATE: As n increases, so do A and $p_{\max}$. Therefore the uncertainty product should also increase, as we have found.

40.35. IDENTIFY: We can model the molecule as a harmonic oscillator. The energy of the photon is equal to the energy difference between the two levels of the oscillator.

SET UP: The energy of a photon is $E_\gamma = hf = hc/\lambda$, and the energy levels of a harmonic oscillator are given by $E_n = (n+\frac{1}{2})\hbar\sqrt{\frac{k'}{m}} = (n+\frac{1}{2})\hbar\omega.$

EXECUTE: **(a)** The photon's energy is $E_\gamma = \frac{hc}{\lambda} = \frac{(6.63\times10^{-34}\text{ J}\cdot\text{s})(3.00\times10^{8}\text{ m/s})}{5.8\times10^{-6}\text{ m}} = 0.21\text{ eV}.$

(b) The transition energy is $\Delta E = E_{n+1} - E_n = \hbar\omega = \hbar\sqrt{\frac{k'}{m}}$, which gives $\frac{2\pi\hbar c}{\lambda} = \hbar\sqrt{\frac{k'}{m}}$. Solving for k', we get $k' = \frac{4\pi^2c^2m}{\lambda^2} = \frac{4\pi^2(3.00\times10^8\text{ m/s})^2(5.6\times10^{-26}\text{ kg})}{(5.8\times10^{-6}\text{ m})^2} = 5{,}900\text{ N/m}.$

EVALUATE: This would be a rather strong spring in the physics lab.

40.36. IDENTIFY: The energy of the absorbed photon must be equal to the energy difference between the two states.

SET UP and EXECUTE: $\Delta E = \frac{hc}{\lambda} = \frac{(4.136\times10^{-15}\text{ eV}\cdot\text{s})(2.998\times10^{8}\text{ m/s})}{6.35\times10^{-6}\text{ m}} = 0.1953\text{ eV} = \hbar\omega.\ \ \Delta E = \hbar\omega.$

$$E_0 = \frac{\hbar\omega}{2} = \frac{0.1953\text{ eV}}{2} = 0.0976\text{ eV}.$$

EVALUATE: The energy of the photon is not equal to the energy of the ground state, but rather it is the energy *difference* between the two states.

40.37. IDENTIFY: The photon energy equals the transition energy for the atom.

SET UP: According to the energy level equation $E_n = (n+\frac{1}{2})\hbar\omega$, the energy released during the transition between two adjacent levels is twice the ground state energy $E_3 - E_2 = \hbar\omega = 2E_0 = 11.2\text{ eV}.$

EXECUTE: For a photon of energy E,

$$E = hf \Rightarrow \lambda = \frac{c}{f} = \frac{hc}{E} = \frac{(6.63\times10^{-34}\ \text{J}\cdot\text{s})(3.00\times10^{8}\ \text{m/s})}{(11.2\ \text{eV})(1.60\times10^{-19}\ \text{J/eV})} = 111\ \text{nm}.$$

EVALUATE: This photon is in the ultraviolet.

40.38. **IDENTIFY:** The energy of the absorbed (or emitted) photon energy is equal to the energy difference between the levels of the oscillator.

SET UP: The energy levels for a harmonic oscillator are $E_n = (n+\frac{1}{2})\hbar\omega,$ where $\omega = \sqrt{k'/m}.$

EXECUTE: **(a)** The energy difference between *any* two adjacent levels is $\Delta E_{n+1} - \Delta E_n = (n+\frac{3}{2})\hbar\omega - (n+\frac{1}{2})\hbar\omega = \hbar\omega.$ Therefore transitions between *any* adjacent levels will emit (or absorb) photons of the same energy and hence the same wavelength. So the $2 \to 3$ transition absorbs a photon of the same wavelength as the $1 \to 2$ transition, which is λ = 6.50 μm.

(b) Since transitions between adjacent levels emit photons of the same energy, transitions between levels for which *n* differs by 2 will emit energy $\hbar\omega + \hbar\omega = 2\hbar\omega.$ So the photon absorbed in the $1 \to 3$ transition will have twice the energy (and therefore half the wavelength) as the photon in the $1 \to 2$ transition, so its wavelength will be $\frac{1}{2}$ (6.50 μm) = 3.25 μm.

(c) For the $1 \to 2$ transition, the photon energy is $\hbar\omega$ and $\omega = \sqrt{k'/m}$, so

$\hbar\omega$ = energy of photon = hc/λ. This gives $\omega = \sqrt{k'/m} = \dfrac{hc}{\hbar\lambda} = \dfrac{2\pi c}{\lambda} = \dfrac{2\pi(3.00\times10^{8}\ \text{m/s})}{6.50\times10^{-6}\ \text{m}}$

$= 2.90\times10^{14}$ rad/s.

EVALUATE: The frequency of this oscillator would be $f = \omega/2\pi = 4.62\times10^{14}$ Hz, *much* higher than typical classical oscillators.

40.39. **IDENTIFY:** We model the atomic vibration in the crystal as a harmonic oscillator.

SET UP: The energy levels of a harmonic oscillator are given by $E_n = (n+\frac{1}{2})\hbar\sqrt{\dfrac{k'}{m}} = (n+\frac{1}{2})\hbar\omega.$

EXECUTE: **(a)** The ground state energy of a simple harmonic oscillator is $E_0 = \frac{1}{2}\hbar\omega$

$$= \frac{1}{2}\hbar\sqrt{\frac{k'}{m}} = \frac{(1.055\times10^{-34}\ \text{J}\cdot\text{s})}{2}\sqrt{\frac{12.2\ \text{N/m}}{3.82\times10^{-26}\ \text{kg}}} = 9.43\times10^{-22}\ \text{J} = 5.89\times10^{-3}\ \text{eV}.$$

(b) $E_4 - E_3 = \hbar\omega = 2E_0 = 0.0118\ \text{eV},$ so $\lambda = \dfrac{hc}{E} = \dfrac{(6.63\times10^{-34}\ \text{J}\cdot\text{s})(3.00\times10^{8}\ \text{m/s})}{1.88\times10^{-21}\ \text{J}} = 106\ \mu\text{m}.$

(c) $E_{n+1} - E_n = \hbar\omega = 2E_0 = 0.0118\ \text{eV}.$

EVALUATE: These energy differences are much smaller than those due to electron transitions in the hydrogen atom.

40.40. **IDENTIFY:** Compute the ratio specified in the problem.

SET UP: For $n = 0,$ $A = \sqrt{\dfrac{\hbar\omega}{k'}}.$ $\omega = \sqrt{\dfrac{k'}{m}}.$

EXECUTE: **(a)** $\dfrac{|\psi(A)|^2}{|\psi(0)|^2} = \exp\left(-\dfrac{\sqrt{mk'}}{\hbar}A^2\right) = \exp\left(-\sqrt{mk'}\dfrac{\omega}{k'}\right) = e^{-1} = 0.368.$ This is consistent with what is shown in Figure 40.27 in the textbook.

(b) $\dfrac{|\psi(2A)^2|}{|\psi(0)|^2} = \exp\left(-\dfrac{\sqrt{mk'}}{\hbar}(2A)^2\right) = \exp\left(-\sqrt{mk'}\,4\dfrac{\omega}{k'}\right) = e^{-4} = 1.83\times10^{-2}.$ This figure cannot be read this precisely, but the qualitative decrease in amplitude with distance is clear.

EVALUATE: The wave function decays exponentially as *x* increases beyond $x = A.$

40.41. **IDENTIFY:** We know the wave function of a particle in a box.

SET UP and **EXECUTE:** **(a)** $\Psi(x,t)=\frac{1}{\sqrt{2}}\psi_1(x)e^{-iE_1t/\hbar}+\frac{1}{\sqrt{2}}\psi_3(x)e^{-iE_3t/\hbar}$.

$$\Psi^*(x,t)=\frac{1}{\sqrt{2}}\psi_1(x)e^{+iE_1t/\hbar}+\frac{1}{\sqrt{2}}\psi_3(x)e^{+iE_3t/\hbar}.$$

$|\Psi(x,t)|^2=\frac{1}{2}[\psi_1^2+\psi_3^2+\psi_1\psi_3(e^{i(E_3-E_1)t/\hbar}+e^{-i(E_3-E_1)t/\hbar})]=\frac{1}{2}\left[\psi_1^2+\psi_3^2+2\psi_1\psi_3\cos\left(\frac{[E_3-E_1]t}{\hbar}\right)\right]$.

$\psi_1=\sqrt{\frac{2}{L}}\sin\left(\frac{\pi x}{L}\right)$. $\psi_3=\sqrt{\frac{2}{L}}\sin\left(\frac{3\pi x}{L}\right)$. $E_3=\frac{9\pi^2\hbar^2}{2mL^2}$ and $E_1=\frac{\pi^2\hbar^2}{2mL^2}$, so $E_3-E_1=\frac{4\pi^2\hbar^2}{mL^2}$.

$|\Psi(x,t)|^2=\frac{1}{L}\left[\sin^2\left(\frac{\pi x}{L}\right)+\sin^2\left(\frac{3\pi x}{L}\right)+2\sin\left(\frac{\pi x}{L}\right)\sin\left(\frac{3\pi x}{L}\right)\cos\left(\frac{4\pi^2\hbar t}{mL^2}\right)\right]$. At $x=L/2$,

$\sin\left(\frac{\pi x}{L}\right)=\sin\left(\frac{\pi}{2}\right)=1$. $\sin\left(\frac{3\pi x}{L}\right)=\sin\left(\frac{3\pi}{2}\right)=-1$. $|\Psi(x,t)|^2=\frac{2}{L}\left[1-\cos\left(\frac{4\pi^2\hbar t}{mL^2}\right)\right]$.

(b) $\omega_{\text{osc}}=\frac{E_3-E_1}{\hbar}=\frac{4\pi^2\hbar}{mL^2}$.

EVALUATE: Note that $\Delta E=\hbar\omega$.

40.42. **IDENTIFY:** In this problem, we model the hydrogen as an electron in a box.

SET UP: $E=hc/\lambda$.

EXECUTE: **(a)** We want the photon energies. $E_{656}=hc/\lambda=hc/(656\text{ nm})=1.89\text{ eV}$. Using the other wavelenghs in the same way gives $E_{486}=2.55\text{ eV}$, $E_{434}=2.86\text{ eV}$, $E_{410}=3.03\text{ eV}$.

(b) We want the minimum n_i. The transitions must all end on a lower state. The lowest possible ones are n = 1, 2, 3, 4, so the first state above that is n = 5.

(c) We want $\mathcal{E}$. Using $n_\text{i}=5$, the final states are n_f = 4, 3, 2, and 1. We follow the instruction in the problem for the possible transitions and find that the transitions 5 → 4, 5 → 3, 5 → 2, and 5 → 1. The greater the difference between n_i and n_f, the greater the photon energy E. Following the directions in the problem, we have

$$5\to4:\quad \mathcal{E}=\frac{E}{n_\text{i}^2-n_\text{f}^2}=\frac{1.89\text{ eV}}{5^2-4^2}=0.210\text{ eV}$$

$$5\to3:\quad \mathcal{E}=\frac{E}{n_\text{i}^2-n_\text{f}^2}=\frac{2.55\text{ eV}}{5^2-3^2}=0.519\text{ eV}$$

$$5\to2:\quad \mathcal{E}=\frac{E}{n_\text{i}^2-n_\text{f}^2}=\frac{2.86\text{ eV}}{5^2-2^2}=0.136\text{ eV}$$

$$5\to1:\quad \mathcal{E}=\frac{E}{n_\text{i}^2-n_\text{f}^2}=\frac{3.03\text{ eV}}{5^2-1^2}=0.158\text{ eV}$$

Averaging the results gives $\mathcal{E}$ = 0.2 eV.

(d) We want L. $E_n=n^2h^2/8mL^2=n^2\mathcal{E}$ gives $\mathcal{E}=h^2/8mL^2$. Solving for L and using $\mathcal{E}$ = 0.2 eV gives L = 2 nm.

(e) Using $L/2a_0$ with L = 2 nm gives a ratio of 18.

EVALUATE: Our result gives L is about 18 times the diameter of a hydrogen atom, so the particle in a box model is not very good.

40.43. **IDENTIFY:** Let I refer to the region $x<0$ and let II refer to the region $x>0$, so

$\psi_I(x)=Ae^{ik_1x}+Be^{-ik_1x}$ and $\psi_{II}(x)=Ce^{ik_2x}$. Set $\psi_I(0)=\psi_{II}(0)$ and $\frac{d\psi_I}{dx}=\frac{d\psi_{II}}{dx}$ at $x=0$.

SET UP: $\frac{d}{dx}(e^{ikx}) = ike^{ikx}$.

EXECUTE: $\psi_I(0) = \psi_{II}(0)$ gives $A + B = C$. $\frac{d\psi_I}{dx} = \frac{d\psi_{II}}{dx}$ at $x = 0$ gives $ik_1A - ik_1B = ik_2C$. Solving this pair of equations for B and C gives $B = \left(\frac{k_1 - k_2}{k_1 + k_2}\right)A$ and $C = \left(\frac{2k_2}{k_1 + k_2}\right)A$.

EVALUATE: The probability of reflection is $R = \frac{B^2}{A^2} = \frac{(k_1 - k_2)^2}{(k_1 + k_2)^2}$. The probability of transmission is $T = \frac{C^2}{A^2} = \frac{4k_1^2}{(k_1 + k_2)^2}$. Note that $R + T = 1$.

40.44. IDENTIFY: The probability of finding the particle between x_1 and x_2 is $\int_{x_1}^{x_2} |\psi|^2\, dx$.

SET UP: For the ground state $\psi_1 = \sqrt{\frac{2}{L}}\sin\frac{\pi x}{L}$. $\sin^2\theta = \frac{1}{2}(1 - \cos 2\theta)$. $\int \cos\alpha x\, dx = \frac{1}{\alpha}\sin\alpha x$.

EXECUTE: **(a)** $\frac{2}{L}\int_0^{L/4} \sin^2\frac{\pi x}{L}dx = \frac{2}{L}\int_0^{L/4}\frac{1}{2}\left(1 - \cos\frac{2\pi x}{L}\right)dx = \frac{1}{L}\left(x - \frac{L}{2\pi}\sin\frac{2\pi x}{L}\right)_0^{L/4} = \frac{1}{4} - \frac{1}{2\pi}$, which is about 0.0908.

(b) Repeating with limits of $L/4$ and $L/2$ gives $\frac{1}{L}\left(x - \frac{L}{2\pi}\sin\frac{2\pi x}{L}\right)_{L/4}^{L/2} = \frac{1}{4} + \frac{1}{2\pi}$, about 0.409.

(c) The particle is much likely to be nearer the middle of the box than the edge.

EVALUATE: **(d)** The results sum to exactly $\frac{1}{2}$. Since the probability of the particle being anywhere in the box is unity, the probability of the particle being found between $x = L/2$ and $x = L$ is also $\frac{1}{2}$. This means that the particle is as likely to be between $x = 0$ and $L/2$ as it is to be between $x = L/2$ and $x = L$.

(e) These results are consistent with Figure 40.12b in the textbook. This figure shows a greater probability near the center of the box. It also shows symmetry of $|\psi|^2$ about the center of the box.

40.45. IDENTIFY and **SET UP:** The energy levels are given by the equation $E_n = \frac{n^2h^2}{8mL^2}$. Calculate ΔE for the transition and set $\Delta E = hc/\lambda$, the energy of the photon.

EXECUTE: **(a)** Ground level, $n = 1, E_1 = \frac{h^2}{8mL^2}$. First excited level, $n = 2, E_2 = \frac{4h^2}{8mL^2}$. The transition energy is $\Delta E = E_2 - E_1 = \frac{3h^2}{8mL^2}$. Set the transition energy equal to the energy hc/λ of the emitted photon. This gives $\frac{hc}{\lambda} = \frac{3h^2}{8mL^2}$. $\lambda = \frac{8mcL^2}{3h} = \frac{8(9.109\times10^{-31}\text{ kg})(2.998\times10^8\text{ m/s})(4.18\times10^{-9}\text{ m})^2}{3(6.626\times10^{-34}\text{ J}\cdot\text{s})}$.

$\lambda = 1.92\times10^{-5}\text{ m} = 19.2\ \mu\text{m}$.

(b) Second excited level has $n = 3$ and $E_3 = \frac{9h^2}{8mL^2}$. The transition energy is

$\Delta E = E_3 - E_2 = \frac{9h^2}{8mL^2} - \frac{4h^2}{8mL^2} = \frac{5h^2}{8mL^2}$. $\frac{hc}{\lambda} = \frac{5h^2}{8mL^2}$, so $\lambda = \frac{8mcL^2}{5h} = \frac{3}{5}(19.2\ \mu\text{m}) = 11.5\ \mu\text{m}$.

EVALUATE: The energy spacing between adjacent levels increases with n, and this corresponds to a shorter wavelength and more energetic photon in part (b) than in part (a).

40.46. **IDENTIFY:** The probability is $|\psi|^2\,dx$, with ψ evaluated at the specified value of x.

SET UP: For the ground state, the normalized wave function is $\psi_1 = \sqrt{2/L}\,\sin(\pi x/L)$.

EXECUTE: **(a)** $(2/L)\sin^2(\pi/4)dx = dx/L$.

(b) $(2/L)\sin^2(\pi/2)dx = 2dx/L$.

(c) $(2/L)\sin^2(3\pi/4) = dx/L$.

EVALUATE: Our results agree with Figure 40.12b in the textbook. $|\psi|^2$ is largest at the center of the box, at $x = L/2$. $|\psi|^2$ is symmetric about the center of the box, so is the same at $x = L/4$ as at $x = 3L/4$.

40.47. **IDENTIFY** and **SET UP:** The normalized wave function for the $n = 2$ first excited level is $\psi_2 = \sqrt{\frac{2}{L}}\sin\left(\frac{2\pi x}{L}\right)$. $P = |\psi(x)|^2\,dx$ is the probability that the particle will be found in the interval x to $x + dx$.

EXECUTE: **(a)** $x = L/4$.

$$\psi(x) = \sqrt{\frac{2}{L}}\sin\left(\left(\frac{2\pi}{L}\right)\left(\frac{L}{4}\right)\right) = \sqrt{\frac{2}{L}}\sin\left(\frac{\pi}{2}\right) = \sqrt{\frac{2}{L}}.$$

$$P = (2/L)dx.$$

(b) $x = L/2$.

$$\psi(x) = \sqrt{\frac{2}{L}}\sin\left(\left(\frac{2\pi}{L}\right)\left(\frac{L}{2}\right)\right) = \sqrt{\frac{2}{L}}\sin(\pi) = 0.$$

$$P = 0.$$

(c) $x = 3L/4$.

$$\psi(x) = \sqrt{\frac{2}{L}}\sin\left(\left(\frac{2\pi}{L}\right)\left(\frac{3L}{4}\right)\right) = \sqrt{\frac{2}{L}}\sin\left(\frac{3\pi}{2}\right) = -\sqrt{\frac{2}{L}}.$$

$$P = (2/L)dx.$$

EVALUATE: Our results are consistent with the $n = 2$ part of Figure 40.12 in the textbook. $|\psi|^2$ is zero at the center of the box and is symmetric about this point.

40.48. **IDENTIFY:** This problem deals with quantum mechanical tunneling.

SET UP and **EXECUTE:** **(a)** We want the average energy per electron. $\Delta U = q\Delta V$ gives $E = eV = e(5\text{ V}) = 5\text{ eV}$.

(b) $U_0 = q\Delta V = e(12\text{ V}) = 12\text{ eV}$.

(c) We want the probability of tunneling, which is $T = Ge^{-2\kappa L}$, where

$$G = 16\frac{E}{U_0}\left(1 - \frac{E}{U_0}\right) \quad \kappa = \frac{\sqrt{2m(U_0 - E)}}{\hbar}.$$

Using E and U_0 from parts (a) and (b), we get $G = 3.89$ and $\kappa = 1.354 \times 10^{10}\text{ m}^{-1}$. Using the equation for T gives a tunneling probability of $T = 6.74 \times 10^{-12}$.

(d) We want the tunneling current. The current density is $J = nev$. On the R side the number of electrons is Tn. $I = JA = TneAv$.

(e) We want the effective speed of tunneled electrons. Using the definition of effective speed gives $v = \sqrt{2eV/m}$.

(f) We want the tunneling current. Using the results from (d) and (e) with the given numbers, we get $I = TneAv = Tnea\sqrt{2eV/m} = Tne\pi(d/2)^2\sqrt{2eV/m} = 95\text{ mA}$.

EVALUATE: In part (c) we see that only a small percent of the electrons tunnel through the barrier.

40.49. **IDENTIFY:** The probability of the particle being between x_1 and x_2 is $\int_{x_1}^{x_2} |\psi|^2\, dx$, where ψ is the normalized wave function for the particle.

(a) SET UP: The normalized wave function for the ground state is $\psi_1 = \sqrt{\dfrac{2}{L}}\sin\left(\dfrac{\pi x}{L}\right)$.

EXECUTE: The probability P of the particle being between $x = L/4$ and $x = 3L/4$ is $P = \int_{L/4}^{3L/4} |\psi_1|^2 dx = \dfrac{2}{L}\int_{L/4}^{3L/4} \sin^2\left(\dfrac{\pi x}{L}\right)dx$. Let $y = \pi x/L;\, dx = (L/\pi)\,dy$ and the integration limits become $\pi/4$ and $3\pi/4$.

$$P = \frac{2}{L}\left(\frac{L}{\pi}\right)\int_{\pi/4}^{3\pi/4} \sin^2 y\, dy = \frac{2}{\pi}\left[\frac{1}{2}y - \frac{1}{4}\sin 2y\right]_{\pi/4}^{3\pi/4}.$$

$$P = \frac{2}{\pi}\left[\frac{3\pi}{8} - \frac{\pi}{8} - \frac{1}{4}\sin\left(\frac{3\pi}{2}\right) + \frac{1}{4}\sin\left(\frac{\pi}{2}\right)\right].$$

$P = \dfrac{2}{\pi}\left(\dfrac{\pi}{4} - \dfrac{1}{4}(-1) + \dfrac{1}{4}(1)\right) = \dfrac{1}{2} + \dfrac{1}{\pi} = 0.818.$ (Note: The integral formula $\int \sin^2 y\, dy = \dfrac{1}{2}y - \dfrac{1}{4}\sin 2y$ was used.)

(b) SET UP: The normalized wave function for the first excited state is $\psi_2 = \sqrt{\dfrac{2}{L}}\sin\left(\dfrac{2\pi x}{L}\right)$.

EXECUTE: $P = \int_{L/4}^{3L/4} |\psi_2|^2 dx = \dfrac{2}{L}\int_{L/4}^{3L/4} \sin^2\left(\dfrac{2\pi x}{L}\right)dx$. Let $y = 2\pi x/L;\, dx = (L/2\pi)\,dy$ and the integration limits become $\pi/2$ and $3\pi/2$.

$$P = \frac{2}{L}\left(\frac{L}{2\pi}\right)\int_{\pi/2}^{3\pi/2} \sin^2 y\, dy = \frac{1}{\pi}\left[\frac{1}{2}y - \frac{1}{4}\sin 2y\right]_{\pi/2}^{3\pi/2} = \frac{1}{\pi}\left(\frac{3\pi}{4} - \frac{\pi}{4}\right) = 0.500.$$

EVALUATE: **(c)** These results are consistent with Figure 40.11b in the textbook. That figure shows that $|\psi|^2$ is more concentrated near the center of the box for the ground state than for the first excited state; this is consistent with the answer to part (a) being larger than the answer to part (b). Also, this figure shows that for the first excited state half the area under $|\psi|^2$ curve lies between $L/4$ and $3L/4$, consistent with our answer to part (b).

40.50. **IDENTIFY:** We start with the penetration distance formula given in the problem.

SET UP: The given formula is $\eta = \dfrac{\hbar}{\sqrt{2m(U_0 - E)}}$.

EXECUTE: **(a)** Substitute the given numbers into the formula:

$$\eta = \frac{\hbar}{\sqrt{2m(U_0 - E)}} = \frac{1.055\times 10^{-34}\ \text{J}\cdot\text{s}}{\sqrt{2(9.11\times 10^{-31}\ \text{kg})(20\ \text{eV} - 13\ \text{eV})(1.602\times 10^{-19}\ \text{J/eV})}} = 7.4\times 10^{-11}\ \text{m}.$$

(b) $\eta = \dfrac{1.055\times 10^{-34}\ \text{J}\cdot\text{s}}{\sqrt{2(1.67\times 10^{-27}\ \text{kg})(30\ \text{MeV} - 20\ \text{MeV})(1.602\times 10^{-13}\ \text{J/MeV})}} = 1.44\times 10^{-15}\ \text{m}.$

EVALUATE: The penetration depth varies widely depending on the mass and energy of the particle.

40.51. **IDENTIFY:** Carry out the calculations that are specified in the problem.

SET UP: For a free particle, $U(x) = 0$, so Schrödinger's equation becomes $\dfrac{d^2\psi(x)}{dx^2} = -\dfrac{2m}{\hbar^2}E\psi(x)$.

EXECUTE: **(a)** The graph is given in Figure 40.51.

(b) For $x < 0$: $\psi(x) = e^{+\kappa x}$. $\dfrac{d\psi(x)}{dx} = \kappa e^{+\kappa x}$. $\dfrac{d^2\psi(x)}{dx} = \kappa^2 e^{+\kappa x}$. So $\kappa^2 = -\dfrac{2m}{\hbar^2}E \Rightarrow E = -\dfrac{\hbar^2\kappa^2}{2m}$.

(c) For $x > 0$: $\psi(x) = e^{-\kappa x}$. $\dfrac{d\psi(x)}{dx} = -\kappa e^{-\kappa x}$. $\dfrac{d^2\psi(x)}{dx} = \kappa^2 e^{-\kappa x}$. So again $\kappa^2 = -\dfrac{2m}{\hbar^2}E \Rightarrow E = \dfrac{-\hbar^2\kappa^2}{2m}$.

Parts (b) and (c) show $\psi(x)$ satisfies the Schrödinger's equation, provided $E = \dfrac{-\hbar^2\kappa^2}{2m}$.

EVALUATE: **(d)** $\dfrac{d\psi(x)}{dx}$ is discontinuous at $x = 0$. (That is, it is negative for $x > 0$ and positive for $x < 0$.) Therefore, this ψ is not an acceptable wave function; $d\psi/dx$ must be continuous everywhere, except where $U \to \infty$.

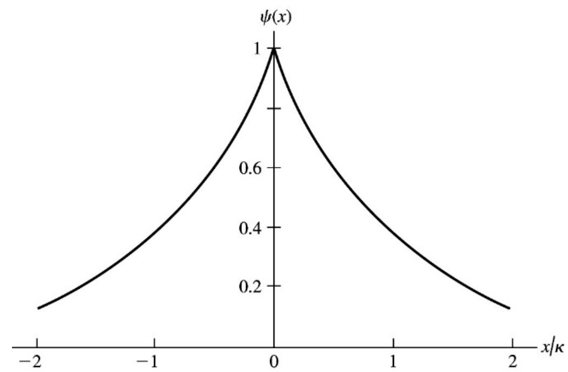

Figure 40.51

40.52. **IDENTIFY:** $T = Ge^{-2\kappa L}$ with $G = 16\dfrac{E}{U_0}\left(1 - \dfrac{E}{U_0}\right)$ and $\kappa = \dfrac{\sqrt{2m(U_0 - E)}}{\hbar}$, so $L = -\dfrac{1}{2\kappa}\ln\left(\dfrac{T}{G}\right)$.

SET UP: $E = 5.5\text{ eV}, U_0 = 10.0\text{ eV}, m = 9.11\times10^{-31}\text{ kg}, \text{and } T = 0.0050.$

EXECUTE: $\kappa = \dfrac{\sqrt{2(9.11\times10^{-31}\text{ kg})(4.5\text{ eV})(1.60\times10^{-19}\text{ J/eV})}}{(1.054\times10^{-34}\text{ J}\cdot\text{s})} = 1.09\times10^{10}\text{ m}^{-1}$ and

$G = 16\dfrac{5.5\text{ eV}}{10.0\text{ eV}}\left(1 - \dfrac{5.5\text{ eV}}{10.0\text{ eV}}\right) = 3.96.$ Therefore the barrier width L is $L = -\dfrac{1}{2\kappa}\ln\left(\dfrac{T}{G}\right)$

$= -\dfrac{1}{2(1.09\times10^{10}\text{ m}^{-1})}\ln\left(\dfrac{0.0050}{3.96}\right) = 3.1\times10^{-10}\text{ m} = 0.31\text{ nm}.$

EVALUATE: The energies here are comparable to those of electrons in atoms, and the barrier width we calculated is on the order of the diameter of an atom.

40.53. **IDENTIFY:** This problem is about a quantum mechanical harmonic oscillator.

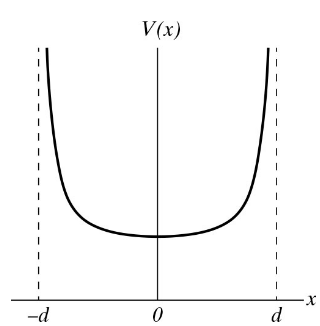

Figure 40.53

SET UP and **EXECUTE:** **(a)** For the sketch, see Figure 40.53.
(b) First combine the terms in the given equation for $V(x)$ to obtain the following:

$$V(x)=\frac{2kq^2}{d}\frac{1}{1-(x/d)^2}, \text{ where } k=1/4\pi\epsilon_0 .$$

Expand the right-hand fraction using $(1+z)^n \approx 1+nz$, where $z \ll 1$, $n=-1$, $z=-(x/d)^2$.

$$V(x)=\frac{2kq^2}{d}\left[1+\frac{x^2}{d^2}\right].$$

Using $q = 6e$ and putting in k gives

$$V(x)=\frac{18e^2}{\pi\epsilon_0 d}+\frac{18e^2}{\pi\epsilon_0 d^3}x^2.$$

(c) We want the spring constant. Using the second term for $V(x)$, we see that

$$V=\frac{1}{2}k'x^2=\frac{18e^2}{\pi\epsilon_0 d^3}x^2$$

$$k=\frac{36e^2}{\pi\epsilon_0 d^3}=265 \text{ N/m}.$$

(d) The classical ground state is $x = 0$, so the energy at this state is

$$V=\frac{18e^2}{\pi\epsilon_0 d}=207 \text{ eV}.$$

(e) We want the energy of the lowest energy photon. Use the quantum energy states.

$$E_0=\frac{1}{2}\hbar\sqrt{\frac{k'}{m}} \text{ and } E_n=\left(n+\frac{1}{2}\right)\hbar\sqrt{\frac{k'}{m}}, \text{ so } E_n=2E_0\left(n+\frac{1}{2}\right).$$

The lowest energy photon is due to a transition from the $n = 1$ state to the $n = 0$ state, so

$$\Delta E=2E_0\left[\left(1+\frac{1}{2}\right)-\left(0+\frac{1}{2}\right)\right]=2E_0=2(0.0379 \text{ eV})=0.0758 \text{ eV}.$$

(f) Use $E=hc/\lambda$ with $E = 0.0758$ eV, giving $\lambda = 16.4\ \mu$m.
EVALUATE: There is obviously a big difference between a quantum oscillator and a classical oscillator.

40.54. **IDENTIFY:** Compare the energy E of the oscillator to the equation $E_n=(n+\frac{1}{2})\hbar\omega$ in order to determine n.
SET UP: At the equilibrium position the potential energy is zero and the kinetic energy equals the total energy.
EXECUTE: **(a)** $E=\frac{1}{2}mv^2=[n+(1/2)]\hbar\omega=[n+(1/2)]hf$, and solving for n,

$$n=\frac{\frac{1}{2}mv^2}{hf}-\frac{1}{2}=\frac{(1/2)(0.020 \text{ kg})(0.480 \text{ m/s})^2}{(6.626\times10^{-34} \text{ J}\cdot\text{s})(1.50 \text{ Hz})}-\frac{1}{2}=2.3\times10^{30}.$$

(b) The difference between energies is $\hbar\omega=hf=(6.63\times10^{-34} \text{ J}\cdot\text{s})(1.50 \text{ Hz})=9.95\times10^{-34} \text{ J}$. This energy is too small to be detected with current technology.
EVALUATE: This oscillator can be described classically; quantum effects play no measurable role.

40.55. **IDENTIFY** and **SET UP:** Calculate the angular frequency ω of the pendulum and apply $E_n=(n+\frac{1}{2})\hbar\omega$ for the energy levels.

EXECUTE: $\omega=\frac{2\pi}{T}=\frac{2\pi}{0.500 \text{ s}}=4\pi \text{ s}^{-1}.$

The ground-state energy is $E_0 = \frac{1}{2}\hbar\omega = \frac{1}{2}(1.055\times10^{-34}\ \text{J}\cdot\text{s})(4\pi\ \text{s}^{-1}) = 6.63\times10^{-34}\ \text{J}$.

$$E_0 = 6.63\times10^{-34}\ \text{J}(1\ \text{eV}/1.602\times10^{-19}\ \text{J}) = 4.14\times10^{-15}\ \text{eV}.$$

$$E_n = (n+\tfrac{1}{2})\hbar\omega.$$

$$E_{n+1} = (n+1+\tfrac{1}{2})\hbar\omega.$$

The energy difference between the adjacent energy levels is

$$\Delta E = E_{n+1} - E_n = \hbar\omega = 2E_0 = 1.33\times10^{-33}\ \text{J} = 8.30\times10^{-15}\ \text{eV}.$$

EVALUATE: These energies are much too small to detect. Quantum effects are not important for ordinary size objects.

40.56. **IDENTIFY:** If the given wave function is a solution to the Schrödinger equation, we will get an identity when we substitute that wave function into the Schrödinger equation.

SET UP: The given wave function is $\psi_1(x) = A_1 x e^{-\alpha^2 x^2/2}$ and the Schrödinger equation is

$$-\frac{\hbar}{2m}\frac{d^2\psi(x)}{dx^2} + \frac{k' x^2}{2}\psi(x) = E\,\psi(x).$$

EXECUTE: **(a)** Start by taking the indicated derivatives: $\psi_1(x) = A_1 x e^{-\alpha^2 x^2/2}$.

$$\frac{d\psi_1(x)}{dx} = -\alpha^2 x^2 A_1 e^{-\alpha^2 x^2/2} + A_1 e^{-\alpha^2 x^2/2}.$$

$$\frac{d^2\psi_1(x)}{dx^2} = -A_1\alpha^2 2x e^{-\alpha^2 x^2/2} - A_1\alpha^2 x^2(-\alpha^2 x)e^{-\alpha^2 x^2/2} + A_1(-\alpha^2 x)e^{-\alpha^2 x^2/2}.$$

$$\frac{d^2\psi_1(x)}{dx^2} = \left[-2\alpha^2 + (\alpha^2)^2 x^2 - \alpha^2\right]\psi_1(x) = \left[-3\alpha^2 + (\alpha^2)^2 x^2\right]\psi_1(x).$$

$$-\frac{\hbar}{2m}\frac{d^2\psi_1(x)}{dx^2} = -\frac{\hbar^2}{2m}\left[-3\alpha^2 + (\alpha^2)^2 x^2\right]\psi_1(x).$$

Eq. (40.44) is $-\frac{\hbar}{2m}\frac{d^2\psi(x)}{dx^2} + \frac{k' x^2}{2}\psi(x) = E\,\psi(x)$. Substituting the above result into that equation gives $-\frac{\hbar^2}{2m}\left[-3\alpha^2 + (\alpha^2)^2 x^2\right]\psi_1(x) + \frac{k' x^2}{2}\psi_1(x) = E\,\psi_1(x)$. Since $\alpha^2 = \frac{m\omega}{\hbar}$ and $\omega = \sqrt{\frac{k'}{m}}$, the coefficient of x^2 is $-\frac{\hbar^2}{2m}(\alpha^2)^2 + \frac{k'}{2} = -\frac{\hbar^2}{2m}\left(\frac{m\omega}{\hbar}\right)^2 + \frac{m\omega^2}{2} = 0$.

(b) $A_1 = \left(\frac{m\omega}{\hbar}\right)^{3/4}\left(\frac{4}{\pi}\right)^{1/4}$.

(c) The probability density function $|\psi|^2$ is $|\psi_1(x)|^2 = A_1^2 x^2 e^{-\alpha^2 x^2}$.

At $x = 0$, $|\psi_1|^2 = 0$. $\frac{d|\psi_1(x)|^2}{dx} = A_1^2 2x e^{-\alpha^2 x^2} + A_1^2 x^2(-\alpha^2 2x)e^{-\alpha^2 x^2} = A_1^2 2x e^{-\alpha^2 x^2} - A_1^2 2x^3\alpha^2 e^{-\alpha^2 x^2}$.

At $x = 0$, $\frac{d|\psi_1(x)|^2}{dx} = 0$. At $x = \pm\frac{1}{\alpha}$, $\frac{d|\psi_1(x)|^2}{dx} = 0$.

$$\frac{d^2|\psi_1(x)|^2}{dx^2} = A_1^2 2e^{-\alpha^2 x^2} + A_1^2 2x(-\alpha^2 2x)e^{-\alpha^2 x^2} - A_1^2 2(3x^2)\alpha^2 e^{-\alpha^2 x^2} - A_1^2 2x^3\alpha^2(-\alpha^2 2x)e^{-\alpha^2 x^2}.$$

$\frac{d^2|\psi_1(x)|^2}{dx^2} = A_1^2 2e^{-\alpha^2 x^2} - A_1^2 4x^2\alpha^2 e^{-\alpha^2 x^2} - A_1^2 6x^2\alpha^2 e^{-\alpha^2 x^2} + A_1^2 8x^4(\alpha^2)^2 e^{-\alpha^2 x^2}$. At $x = 0$,

$\frac{d^2|\psi_1(x)|^2}{dx^2} > 0.$ So at $x = 0,$ the first derivative is zero and the second derivative is positive. Therefore, the probability density function has a minimum at $x = 0.$ At $x = \pm\frac{1}{\alpha},$ $\frac{d^2|\psi_1(x)|^2}{dx^2} < 0.$ So at $x = \pm\frac{1}{\alpha},$ the first derivative is zero and the second derivative is negative. Therefore, the probability density function has maxima at $x = \pm\frac{1}{\alpha},$ corresponding to the classical turning points for $n = 0$ as found in the previous question.

EVALUATE: $\psi_1(x) = A_1 x e^{-\alpha^2 x^2/2}$ is a solution to Eq. (40.44) if $-\frac{\hbar^2}{2m}(-3\alpha^2)\psi_1(x) = E\,\psi_1(x)$ or $E = \frac{3\hbar^2\alpha^2}{2m} = \frac{3\hbar\omega}{2}.$ $E_1 = \frac{3\hbar\omega}{2}$ corresponds to $n = 1$ in Eq. (40.46).

40.57. IDENTIFY: For a standing wave in the box, there must be a node at each wall and $n\left(\frac{\lambda}{2}\right) = L.$

SET UP: $p = \frac{h}{\lambda} \neq,$ so $mv = \frac{h}{\lambda}.$

EXECUTE: **(a)** For a standing wave, $n\lambda = 2L,$ and $E_n = \frac{p^2}{2m} = \frac{(h/\lambda)^2}{2m} = \frac{n^2h^2}{8mL^2}.$

(b) With $L = a_0 = 0.5292\times10^{-10}$ m, $E_1 = 2.15\times10^{-17}$ J $= 134$ eV.

EVALUATE: For a hydrogen atom, E_n is proportional to $1/n^2,$ so this is a very poor model for a hydrogen atom. In particular, it gives very inaccurate values for the separations between energy levels.

40.58. IDENTIFY and **SET UP:** Follow the steps specified in the problem.

EXECUTE: **(a)** As with the particle in a box, $\psi(x) = A\sin kx,$ where A is a constant and $k^2 = 2mE/\hbar^2.$ Unlike the particle in a box, however, k and hence E do not have simple forms.

(b) For $x > L,$ the wave function must have the form of $\psi(x) = Ce^{\kappa x} + De^{-\kappa x}.$ For the wave function to remain finite as $x \to \infty, C = 0.$ The constant $\kappa^2 = 2m(U_0 - E)/\hbar,$ as in $\psi(x) = Ce^{\kappa x} + De^{-\kappa x}.$

(c) At $x = L,$ $A\sin kL = De^{-\kappa L}$ and $kA\cos kL = -\kappa De^{-\kappa L}.$ Dividing the second of these by the first gives $k\cot kL = -\kappa,$ a transcendental equation that must be solved numerically for different values of the length L and the ratio $E/U_0.$

EVALUATE: When $U_0 \to \infty,$ $\kappa \to \infty$ and $\frac{\cos(kL)}{\sin(kL)} \to \infty.$ The solutions become $k = \frac{n\pi}{L}, n = 1, 2, 3,\ldots,$ the same as for a particle in a box.

40.59. IDENTIFY and **SET UP:** The energy levels for an infinite potential well are $E_n = \frac{n^2h^2}{8mL^2} = E_1 n^2.$ The energy of the absorbed photon is equal to the energy difference between the levels. The energy of a photon is $E = hf = hc/\lambda,$ so $\Delta E = hf = E_{n+1} - E_n.$

EXECUTE: **(a)** For the first transition, we have $hf_1 = E_1(n^2 - 1^2),$ and for the second transition we have $hf_2 = E_1[(n+1)^2 - 1^2].$ Taking the ratio of these two equations gives

$$\frac{hf_2}{hf_1} = \frac{16.9}{9.0} = \frac{(n+1)^2 - 1}{n^2 - 1} = \frac{n^2 + 2n + 1 - 1}{n^2 - 1} = \frac{n^2 + 2n}{n^2 - 1}.$$

Rearranging and collecting terms gives the quadratic equation $n^2\left(\frac{16.9}{9.0}-1\right)-2n-\frac{16.9}{9.0}=0.$ Using the quadratic formula and taking the positive root gives $n = 3.0$, so $n = 3$. Therefore the transitions are from the $n = 3$ and $n = 4$ levels to the $n = 1$ level.

(b) Using the $3 \rightarrow 1$ transition with $f_1 = 9.0\times10^{14}$ Hz, we have

$hf_1 = (h^2/8mL^2)(3^2 - 1^2) = h^2/mL^2.$

$$L=\sqrt{\frac{h}{f_1 m}}=\sqrt{\frac{6.626\times10^{-34}\ \text{J}\cdot\text{s}}{(9.0\times10^{14}\ \text{Hz})(9.109\times10^{-31}\ \text{kg})}}=9.0\times10^{-10}\ \text{m}=0.90\ \text{nm}.$$

(c) The longest wavelength is for the smallest energy, and that would be for a transition between $n = 1$ and $n = 2$ levels. Comparing the $1 \rightarrow 3$ transition and the $1 \rightarrow 2$ transition, we have

$$\frac{hf_{1\to2}}{hf_{1\to3}}=\frac{E_1(2^2-1^2)}{E_1(3^2-1^2)} \quad\rightarrow\quad f_{1\to2}=\frac{3}{8}f_{1\to3}=\frac{3}{8}(9.0\times10^{14}\ \text{Hz}).$$

$$\lambda=c/f=\frac{3.00\times10^{8}\ \text{m/s}}{\frac{3}{8}(9.0\times10^{14}\ \text{Hz})}=890\ \text{nm}.$$

EVALUATE: This wavelength is too long to be visible light. The wavelength of the 9.0×10^{14} Hz photon is 333 nm, which is too short to be visible, as is the 16.9×10^{14} Hz photon. So none of these photons will be visible.

40.60. IDENTIFY and **SET UP:** Provided that $T \ll 1$, the probability T of a particle with energy E and mass m tunneling through a potential barrier of width L and height U_0 is $T = Ge^{-2\kappa L}$, where

$$G=16\frac{E}{U_0}\left(1-\frac{E}{U_0}\right)\ \text{and}\ \kappa=\frac{\sqrt{2m(U_0-E)}}{\hbar}.$$

EXECUTE: **(a)** Using the values of E in the table in the problem, we calculate G and κ. For example, for $E = 4.0$ eV, we have $G=16\frac{E}{U_0}\left(1-\frac{E}{U_0}\right)=16\frac{4.0\ \text{eV}}{8.0\ \text{eV}}\left(1-\frac{4.0\ \text{eV}}{8.0\ \text{eV}}\right)=4.0.$

$$U_0-E=8.0\ \text{eV}-4.0\ \text{eV}=4.0\ \text{eV}=6.4\times10^{-19}\ \text{J}.$$

$$\kappa=\frac{\sqrt{2m(U_0-E)}}{\hbar}=\frac{\sqrt{2(9.11\times10^{-31}\ \text{kg})(6.4\times10^{-19}\ \text{J})}}{1.055\times10^{-34}\ \text{J}\cdot\text{s}}=1.02\times10^{10}\ \text{m}^{-1}.$$

Repeating these calculations for the other values of E, and also calculating $\ln(T/G)$, we get the following:

E(eV)	T	G	κ (m^{-1})	$\ln(T/G)$
4.0	2.40×10^{-6}	4.0	1.02×10^{10}	–14.3
5.0	1.50×10^{-5}	3.75	8.87×10^{9}	–12.4
6.0	1.20×10^{-4}	3.0	7.25×10^{9}	–10.1
7.0	1.30×10^{-3}	1.75	5.12×10^{9}	–7.2
7.6	8.10×10^{-3}	0.76	3.24×10^{9}	–4.5

Figure 40.60 shows the graph of $\ln(T/G)$ versus κ. For $T \ll 1$, we have $T = Ge^{-2\kappa L}$, which we can write as $T/G = e^{-2\kappa L}$. Taking natural logarithms of both sides of the equation gives $\ln(T/G) = -2L\,\kappa$. From this last equation, we would expect a graph of $\ln(T/G)$ versus κ to be a straight line with slope equal to $-2L$.

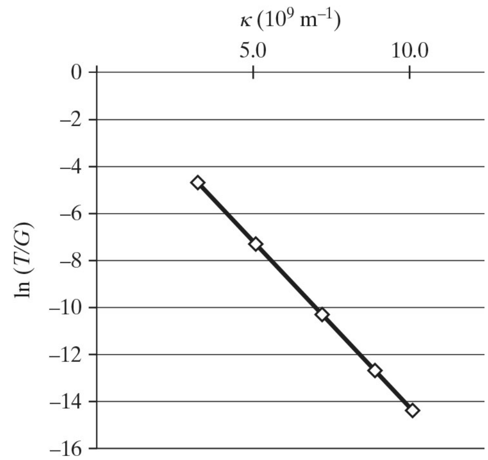

Figure 40.60

(b) The slope of the best-fit straight line for our graph is -1.396×10^{-9} m, so $-2L = -1.396 \times 10^{-9}$ m, which gives $L = 0.698 \times 10^{-9}$ m, which rounds to $L = 0.70$ nm.

EVALUATE: This width is about 7 times the width of a hydrogen atom in the Bohr model.

40.61. IDENTIFY and **SET UP:** The transmission coefficient T is equal to 1 when the width L of the barrier is $L = \frac{1}{2}\lambda,\ \lambda,\ \frac{3}{2}\lambda,\ 2\lambda,\ \ldots = n\lambda/2,$ where $n = 1, 2, 3, \ldots$, and where λ is the de Broglie wavelength of the electron, given by $\lambda = h/p$. The total energy of the electron is $E = U + K$, and $K = p^2/2m$.

EXECUTE: From the condition on λ, we have $\lambda_n = 2L/n$. Therefore $\lambda = h/p = 2L/n$, which gives $p = nh/2L$. The kinetic energy is $K = p^2/2m$, so $K_n = \dfrac{p^2}{2m} = \dfrac{\left(\dfrac{nh}{2L}\right)^2}{2m} = n^2\left(\dfrac{h^2}{8mL^2}\right) = n^2K_1$. The three lowest values of K are for $n = 1$, 2, and 3.

$K_1 = h^2/8mL^2 = (6.626 \times 10^{-34}\ \text{J}\cdot\text{s})^2/[8(9.11 \times 10^{-31}\ \text{kg})(1.8 \times 10^{-10}\ \text{m})^2] = 1.86 \times 10^{-18}\ \text{J} = 11.6$ eV.

The total energy is $E = K + U$, so $E_1 = K_1 + U = 11.6\ \text{eV} + 10\ \text{eV} = 22\ \text{eV}$.

For the $n = 2$ state, we have

$$K_2 = 2^2 K_1 = 4(11.6\ \text{eV}) = 46.4\ \text{eV, so } E_2 = 46.4\ \text{eV} + 10\ \text{eV} = 56\ \text{eV}.$$

For the $n = 3$ state, we have

$K_3 = 3^2 K_1 = 9(11.6\ \text{eV}) = 104.4\ \text{eV, so } E_3 = 104.4\ \text{eV} + 10\ \text{eV} = 114\ \text{eV},$ which rounds to 110 eV.

EVALUATE: We cannot use Eq. (40.42) because T is not small.

40.62. IDENTIFY: This problem deals with the Schrödinger wave equation.

SET UP: $-\dfrac{\hbar^2}{2m}\dfrac{d^2\psi}{dx} = E\psi$

EXECUTE: **(a)** For a free particle, ψ is in the form $\psi = Ae^{\pm in\theta}$. The wave function repeats as θ changes by 2π. If n is an integer, the wave functions must be $\psi_n^+ = A_+e^{+in\theta}$ and $\psi_n^- = A\_e^{-in\theta}$. The – function is for clockwise motion and the + function is for counterclockwise motion.

(b) We normalize the functions to find the coefficients.

$$1 = \int\left|\psi_+\right|^2 dx = \int_0^{2\pi R} A_+^2\, e^{in\theta}e^{-in\theta}\, dx = A_+^2\, 2\pi R.\ A_+ = 1/\sqrt{2\pi R}.$$

The same procedure gives the same value for $A\_$.

(c) We want the energy levels E_n. The wave function must satisfy the time-independent Schrödinger equation. Using $x = R\theta$ for ψ^+ gives the following:

$$-\frac{\hbar^2}{2m}\frac{d^2\psi}{dx} = E\psi$$

$$-\frac{\hbar^2}{2m}\frac{d^2\psi_n^+}{dx^2} = -\frac{\hbar^2}{2m}\frac{d^2\psi_n^+}{R^2\, d\theta^2} = -\frac{\hbar^2}{2mR^2}\frac{d^2}{d\theta^2}\left(A_+e^{in\theta}\right) = -\frac{\hbar^2}{2mR^2}A_+(in)^2e^{in\theta} = -\frac{\hbar^2}{2mR^2}(-n^2)A_+e^{in\theta}$$

The right-hand part of the last equation must be $E\psi$, so we find that

$$E_n = \frac{\hbar^2 n^2}{2mR^2}.$$

(d) We want the time-dependent wave function. We use the following:

$$\omega = E_1/\hbar,\ E_n = n^2E_1 = n^2\hbar\omega,\ \ \Psi(x,t) = \psi(x)e^{-iEt/\hbar}.$$

For Ψ_n^+ we have

$$\Psi_n^+(x,t) = \psi_n^+(x)e^{-iE_nt/\hbar} = A_+e^{in\theta}e^{-iE_nt/\hbar} = \frac{1}{\sqrt{2\pi R}}e^{in(\theta-n\omega t)} = \frac{1}{\sqrt{2\pi R}}e^{in(x/R-n\omega t)}.$$

The same procedure leads to

$$\Psi_n^-(x,t) = \frac{1}{\sqrt{2\pi R}}e^{-in(\theta+n\omega t)} = \frac{1}{\sqrt{2\pi R}}e^{-in(x/R+n\omega t)}.$$

(e) We want the probability density.

$$E_n/\hbar = n^2\omega$$

$$\Psi(x,t) = \frac{1}{\sqrt{2}}\left(\psi_1^+(x)e^{-iE_1t/\hbar} + \psi_2^+(x)e^{-iE_2t/\hbar}\right) = \frac{1}{\sqrt{2}}\left(A_1e^{i\theta}e^{-i\omega t} + A_2e^{2i\theta}e^{-4i\omega t}\right)$$

$$\Psi(x,t) = \frac{1}{\sqrt{2}}\frac{1}{\sqrt{2\pi R}}\left(e^{i(\theta-\omega t)} + e^{2i(\theta-2\omega t)}\right)$$

To find the probability density, we square the wave function and collect terms:

$$\left|\Psi(x,t)\right|^2 = \frac{1}{4\pi R}\left(2 + e^{-i\theta}e^{3i\omega t} + e^{i\theta}e^{-3i\omega t}\right)$$

Now use $e^{\pm i\theta} = \cos\theta \pm i\sin\theta$ to remove the exponentials, giving

$$\left|\Psi(x,t)\right|^2 = \frac{1}{2\pi}(1+\cos\theta\cos 3\omega t + \sin\theta\sin 3\omega t) = \frac{1}{2\pi R}[1+\cos(\theta-3\omega t)]$$

Now use the identity suggested in the problem with $\alpha = \theta - 3\omega t$ to obtain

$$\left|\Psi(x,t)\right|^2 = \frac{1}{\pi R}\cos^2\left(\frac{\theta-3\omega t}{2}\right) = \frac{1}{\pi R}\cos^2\left(\frac{x/R-3\omega t}{2}\right).$$

(f) We want the angular speed of the density peak. The density peak occurs when the probability amplitude is a maximum. This occurs when the cosine factor in the previous result is equal to 1. From this we see that $\theta - 3\omega t = 0$. The angular speed is $\theta/t = 3\omega$.

(g) We want the speed for the electron at the Bohr radius.

$$v = R(\theta/t) = R(3\omega) = 3R\omega.\ \ \omega = E_1/\hbar = \frac{\hbar^2/2mR^2}{\hbar} = \frac{\hbar}{2mR^2}.\ \ v = 3R\omega = 3R\left(\frac{\hbar}{2mR^2}\right) = \frac{3\hbar}{2mR}.$$

Putting in the numbers with $R = a_0 = 5.29 \times 10^{-11}$ m gives $v = 3.28 \times 10^6$ m/s.

Evaluate: This result is fairly close to the value of 2.2×10^6 m/s that Eq. (39.9) gives.

40.63. **Identify:** This problem involves commutators and the Schrödinger equation.

Set Up: $[A, B]f = A(Bf) - B(Af)$. The following operators are defined:

$$a_+ = \frac{1}{\sqrt{2m\hbar\omega}}\left(-\hbar\frac{d}{dx} + m\omega x\right) \text{ and } a_- = \frac{1}{\sqrt{2m\hbar\omega}}\left(+\hbar\frac{d}{dx} + m\omega x\right).$$

EXECUTE: (a) We want $[a_-, a_+]$.

$$[a_-, a_+]f = a_-(a_+ f) - a_+(a_- f) = \frac{1}{\sqrt{2m\hbar\omega}}\frac{1}{\sqrt{2m\hbar\omega}}\left(\hbar\frac{d}{dx} + m\omega x\right)\left[\left(-\hbar\frac{d}{dx} + m\omega x\right)f\right]$$
$$-\frac{1}{\sqrt{2m\hbar\omega}}\frac{1}{\sqrt{2m\hbar\omega}}\left(-\hbar\frac{d}{dx} + m\omega x\right)\left[\left(\hbar\frac{d}{dx} + m\omega x\right)f\right]$$

Carefully carrying out all the operations gives $[a_-, a_+]f = f$, so $[a_-, a_+] = 1$.

(b) We want $[a_+, a_-]\psi$, where ψ is a wave equation, which means that it is a solution to the Schrödinger equation. Follow the procedure in part (a). The solution is sketched out below.

$$a_+a_-\psi = \frac{1}{\sqrt{2m\hbar\omega}}\left(-\hbar\frac{d}{dx} + m\omega x\right)\left[\frac{1}{\sqrt{2m\hbar\omega}}\left(\hbar\frac{d}{dx} + m\omega x\right)\psi\right].$$

$$a_+a_-\psi = \frac{1}{\sqrt{2m\hbar\omega}}\left(-\hbar\frac{d}{dx} + m\omega x\right)\left(\hbar\frac{d\psi}{dx} + m\omega x\psi\right).$$

$$a_+a_-\psi = \frac{1}{\sqrt{2m\hbar\omega}}\left(-\hbar^2\frac{d^2\psi}{dx^2} - \hbar m\omega\frac{d(x\psi)}{dx} + m\omega x\frac{d\psi}{dx} + m^2\omega^2x^2\psi\right).$$

$$a_+a_-\psi = \frac{1}{\sqrt{2m\hbar\omega}}\left(-\hbar^2\frac{d^2\psi}{dx^2} - \hbar m\omega\psi + m^2\omega^2x^2\psi\right) = \frac{1}{\hbar\omega}\left(-\frac{\hbar^2}{2m}\psi'' + \frac{m\omega^2x^2}{2}\psi\right) - \frac{1}{2}\psi.$$

(c) Use the results of part (b) and the Schrödinger equation given with this problem. Note that the term in parentheses in the answer to (b) is the Schrödinger equation. Solving for it gives

$$\hbar\omega\left(a_+a_-\psi + \frac{1}{2}\psi\right) = -\frac{\hbar^2}{2m}\psi'' + \frac{m\omega^2x^2}{2}\psi$$

Therefore the operator H must be

$$H = \hbar\omega\left(a_+a_- + \frac{1}{2}\right).$$

(d) We want $[H, a_\pm]$. Using $[H, a_\pm]f = H(a_+ f) - a_+(Hf)$ gives

$$[H, a_+]f = H(a_+ f) - a_+\left[\hbar\omega\left(a_+a_- + \frac{1}{2}\right)\right]f = \hbar\omega\left[\left(\frac{1}{2} + a_+a_-\right)(a_+ f) - a_+\frac{f}{2} - a_+(a_+a_- f)\right]$$

$$[H, a_+]f = \hbar\omega(a_+)(a_-a_+ - a_+a_-)f = \hbar\omega a_+ f.$$

The same procedure leads to a similar result for $[H, a_\pm]$. Therefore the commutators are

$$[H, a_+] = \hbar\omega a_+ \text{ and } [H, a] = \hbar\omega a_-.$$

(e) We want to relate E_{n+1} to E_n.

For the n state: $H\Psi_n = E_n\Psi_n$

For the $n+1$ state: $H\psi_{n+1} = E_{n+1}\psi_{n+1}$ and $\psi_{n+1} = a_+\psi_n$, so $H\psi_{n+1} = Ha_+\psi_n$

$$[H, a_+]\psi_n = Ha_+\psi_n - a_+H\psi_n \text{ gives } Ha_+\psi_n = [H, a_+]\psi_n + a_+H\psi_n$$

$$H\psi_{n+1} = Ha_+\psi_n = ([H, a_+] + a_+H)\psi_n$$

Using the result from part (d), we can write this result as

$$H\psi_{n+1} = a_+H\psi_n + \hbar\omega a_+\psi_n$$

$$H\psi_n = E_n\psi_n \text{ and } \psi_{n+1} = a_+\psi_n \text{ gives } H\psi_{n+1} = E_n\psi_{n+1} + \hbar\omega\psi_{n+1} = (E_n + \hbar\omega)\psi_{n+1}$$

This result means that $E_{n+1} = E_n + \hbar\omega$.

(f) We want the ground state energy E_0.

Using $H\psi_0 = E_0\psi_0$ gives $\hbar\omega\left(\frac{1}{2}+a_+a_-\right)\psi_0 = E_0\psi_0$. Given that $a_-\psi_0 = 0$, we have

$\frac{1}{2}\hbar\omega\psi_0 = E_0\psi_0$, which tells us that $E_0 = \frac{1}{2}\hbar\omega$.

(g) We want the energy levels E_n. From (e) we know that the energy of each state is $\hbar\omega$ higher than the previous state, and from (f) we know that the energy of the lowest state is $\hbar\omega/2$. Therefore the energies are

$$E_0 = \hbar\omega\left(\frac{1}{2}\right), E_1 = \hbar\omega\left(1+\frac{1}{2}\right), E_2 = \hbar\omega\left(2+\frac{1}{2}\right), E_3 = \hbar\omega\left(3+\frac{1}{2}\right), \cdots E_n = \hbar\omega\left(n+\frac{1}{2}\right).$$

EVALUATE: The use of the method developed here depends on selecting appropriate operators $a_\pm$.

40.64. **IDENTIFY** and **SET UP:** Follow the steps specified in the problem.

EXECUTE: **(a)** $E = K + U(x) = \frac{p^2}{2m} + U(x) \Rightarrow p = \sqrt{2m(E-U(x))}$. $\lambda = \frac{h}{p} \Rightarrow \lambda(x) = \frac{h}{\sqrt{2m(E-U(x))}}$.

(b) As $U(x)$ gets larger (i.e., $U(x)$ approaches E from below—recall $k \geq 0$), $E-U(x)$ gets smaller, so $\lambda(x)$ gets larger.

(c) When $E = U(x)$, $E - U(x) = 0$, so $\lambda(x) \to \infty$.

(d) $\int_a^b \frac{dx}{\lambda(x)} = \int_a^b \frac{dx}{h/\sqrt{2m(E-U(x))}} = \frac{1}{h}\int_a^b \sqrt{2m(E-U(x))}\,dx = \frac{n}{2} \Rightarrow \int_a^b \sqrt{2m(E-U(x))}\,dx = \frac{hn}{2}$.

(e) $U(x) = 0$ for $0 < x < L$ with classical turning points at $x = 0$ and $x = L$. So,

$\int_a^b \sqrt{2m[E-U(x)]}\,dx = \int_0^L \sqrt{2mE}\,dx = \sqrt{2mE}\int_0^L dx = \sqrt{2mE}L$. So, from part (d),

$\sqrt{2mE}L = \frac{hn}{2} \Rightarrow E = \frac{1}{2m}\left(\frac{hn}{2L}\right)^2 = \frac{h^2n^2}{8mL^2}$.

EVALUATE: **(f)** Since $U(x) = 0$ in the region between the turning points at $x = 0$ and $x = L$, the result is the *same* as part (e). The height U_0 never enters the calculation. WKB is best used with *smoothly* varying potentials $U(x)$.

40.65. **IDENTIFY:** Perform the calculations specified in the problem.

SET UP: $U(x) = \frac{1}{2}k'x^2$.

EXECUTE: **(a)** At the turning points $E = \frac{1}{2}k'x_{\text{TP}}^2 \Rightarrow x_{\text{TP}} = \pm\sqrt{\frac{2E}{k'}}$.

(b) $\int_{-\sqrt{2E/k'}}^{+\sqrt{2E/k'}} \sqrt{2m(E-\frac{1}{2}k'x^2)}dx = \frac{nh}{2}$. To evaluate the integral, we want to get it into a form that matches the standard integral given. $\sqrt{2m\left(E-\frac{1}{2}k'x^2\right)} = \sqrt{2mE - mk'x^2} = \sqrt{mk'}\sqrt{\frac{2mE}{mk'} - x^2} = \sqrt{mk'}\sqrt{\frac{2E}{k'} - x^2}$.

Letting $A^2 = \frac{2E}{k'}$, $a = -\sqrt{\frac{2E}{k'}}$, *and* $b = +\sqrt{\frac{2E}{k'}}$

$$\Rightarrow \sqrt{mk'}\int_a^b \sqrt{A^2 - x^2}\,dx = 2\frac{\sqrt{mk'}}{2}\left[x\sqrt{A^2-x^2} + A^2 \arcsin\left(\frac{x}{|A|}\right)\right]\Bigg|_0^b$$

$$= \sqrt{mk'}\left[\sqrt{\frac{2E}{k'}}\sqrt{\frac{2E}{k'} - \frac{2E}{k'}} + \frac{2E}{k'}\arcsin\left(\frac{\sqrt{2E/k'}}{\sqrt{2E/k'}}\right)\right] = \sqrt{mk'}\,\frac{2E}{k'}\arcsin(1) = 2E\sqrt{\frac{m}{k'}}(\tfrac{1}{2}).$$

Using WKB, this is equal to $\frac{hn}{2}$, so $E\sqrt{\frac{m}{k'}}\pi = \frac{hn}{2}$. Recall $\omega = \sqrt{\frac{k'}{m}}$, so $E = \frac{h}{2\pi}\omega n = \hbar\omega n.$

EVALUATE: **(c)** We are missing the zero-point-energy offset of $\frac{\hbar\omega}{2}$ (recall $E = \hbar\omega(n+\frac{1}{2})$). It underestimates the energy. However, our approximation isn't bad at all!

40.66. **IDENTIFY** and **SET UP:** Perform the calculations specified in the problem.

EXECUTE: **(a)** At the turning points $E = A|x_{\text{TP}}| \Rightarrow x_{\text{TP}} = \pm\frac{E}{A}.$

(b) $\int_{-E/A}^{+E/A}\sqrt{2m(E - A|x|)}dx = 2\int_0^{E/A}\sqrt{2m(E - Ax)}\,dx.$ Let $y = 2m(E - Ax)$

$\Rightarrow dy = -2mA\,dx$ when $x = \frac{E}{A}$, $y = 0$, and when $x = 0$, $y = 2mE$. So

$2\int_0^{\frac{E}{A}}\sqrt{2m(E - Ax)}dx = -\frac{1}{mA}\int_{2mE}^{0}y^{1/2}dy = -\frac{2}{3mA}y^{3/2}\Big|_{2mE}^{0} = \frac{2}{3mA}(2mE)^{3/2}.$ Using WKB, this is equal to $\frac{hn}{2}$. So, $\frac{2}{3mA}(2mE)^{3/2} = \frac{hn}{2} \Rightarrow E = \frac{1}{2m}\left(\frac{3mAh}{4}\right)^{2/3}n^{2/3}.$

EVALUATE: **(c)** The difference in energy decreases between successive levels. For example:
$1^{2/3} - 0^{2/3} = 1, 2^{2/3} - 1^{2/3} = 0.59, 3^{3/2} - 2^{3/2} = 0.49, \ldots$

- A sharp ∞ step gave ever-increasing level differences $(\sim n^2)$.
- A parabola $(\sim x^2)$ gave evenly spaced levels $(\sim n)$.
- Now, a linear potential $(\sim x)$ gives ever-decreasing level differences $(\sim n^{2/3})$.

Roughly speaking, if the curvature of the potential (~ second derivative) is bigger than that of a parabola, then the level differences will increase. If the curvature is less than a parabola, the differences will decrease.

40.67. **IDENTIFY** and **SET UP:** The energy levels are $E_{m,n} = (m^2 + n^2)(\pi^2\hbar^2)/2ML^2.$

EXECUTE: For a fixed value of m, the spacing between adjacent energy levels is
$\Delta E = [(m^2 + (n+1)^2 - (m^2 + n^2)](\pi^2\hbar^2)/2ML^2 = (2n+1)(\pi^2\hbar^2)/2ML^2.$ As the value of L is decreased, the spacing between adjacent levels increases. In this model, L is the size of the dot, so choice (c) is correct.

EVALUATE: We could also have kept n fixed and varied m by 1.

40.68. **IDENTIFY** and **SET UP:** The energy levels are $E_{m,n} = (m^2 + n^2)(\pi^2\hbar^2)/2ML^2.$ $\Delta E = \frac{hc}{\lambda}$ for the photon emitted during a transition through energy difference ΔE.

EXECUTE: Since $E \propto 1/L^2$, it is also the case that $\Delta E \propto 1/L^2$, and we know that $\Delta E = \frac{hc}{\lambda}.$

Therefore
$\lambda \propto L^2$. If $L \to 1.1L$, $\lambda \to (1.1)^2\lambda$. So in this case, $\lambda \to (1.1)^2(550\text{ nm}) = 666\text{ nm} \approx 670\text{ nm}$, which is choice (b).

EVALUATE: Because λ is proportional to the *square* of L instead of just L, a 10% change in L produces around a 20% change in λ.

40.69. **IDENTIFY** and **SET UP:** The energy levels are $E_{m,n} = (m^2 + n^2)(\pi^2\hbar^2)/2ML^2$. $\Delta E = \dfrac{hc}{\lambda}$ for the photon emitted during a transition through energy difference ΔE.

EXECUTE: Since $\Delta E \propto 1/M$ and $\Delta E = \dfrac{hc}{\lambda}$, it follows that $\lambda \propto 1/M$. Since $\lambda_1 > \lambda_2$, it is true that $M_1 > M_2$, which makes choice (a) correct.

EVALUATE: When M is large, the energy difference between states is small, so the energy of an emitted (or absorbed) photon is small, so its wavelength is large.

40.70. **IDENTIFY:** Apply the Heisenberg uncertainty principle, stated in terms of energy and time.

SET UP: $\Delta E \Delta t \geq \hbar/2$.

EXECUTE: Solving for ΔE gives $\Delta E \geq \dfrac{\hbar}{2\Delta t}$. Therefore increasing the lifetime of the excited states results in a smaller energy spread because ΔE is small, meaning that the energies are more well-defined. Therefore choice (a) is correct.

EVALUATE: A long lifetime does not imply that the energy is small; but it does tell us that the *uncertainty* in the energy is small.

41

QUANTUM MECHANICS II: ATOMIC STRUCTURE

VP41.1.1. **IDENTIFY:** This problem involves a particle in a three-dimensional cubical box.

SET UP: Eq. (41.15) gives the wave function of the particle, and the square of the wave function is the probability density.

EXECUTE: **(a)** We want to find where the probability distribution function is zero.

$$\left|\psi_{2,1,3}\right|^2 = |C|^2 \sin^2\frac{2\pi x}{L}\sin^2\frac{\pi y}{L}\sin^2\frac{3\pi z}{L} = 0.$$

$2\pi x/L = \pi : x = L/2$

$\pi y/L = \pi : y = L$ (none inside the box)

$3\pi z/L = m\pi : z = mL/3 = L/3$ and $2L/3$.

(b) We want the probability that the particle will be found within the range $0 \le x \le L/3$. Use results from Example 41.1. $C = (2/L)^{3/2}$. The probability is given by

$$P = |C|^2\int_0^{L/3}\sin^2\frac{2\pi x}{L}dx\int_0^L\sin^2\frac{\pi y}{L}dy\int_0^L\sin^2\frac{3\pi z}{L}dz.$$

The y and z integrals are each equal to $L/2$, and the x integral is $L/6 - (L/8\pi)\sin 4\pi/3 = 0.201L$. The probability is $P = [(2/L)^{3/2}]^2(0.201L)(L/2)(L/2) = 0.402$.

EVALUATE: The probability of finding the particle between $x = 0$ and $x = L/3$ is about 40%, so the probability of finding it between $x = L/3$ and L is about 60%.

VP41.1.2. **IDENTIFY:** This problem involves a particle in a three-dimensional cubical box.

SET UP: Eq. (41.15) gives the wave function of the particle, and the square of the wave function is the probability density. We want the probability of finding the particle in the region $L/4 \le x \le 3L/4$.

EXECUTE: **(a)** The state is (1,1,1). We integrate using results from Example 41.1. $C = (2/L)^{3/2}$.

$$P = |C|^2\int_{L/4}^{3L/4}\sin^2\frac{\pi x}{L}dx\int_0^L\sin^2\frac{\pi y}{L}dy\int_0^L\sin^2\frac{\pi z}{L}dz.$$

The second two integrals are each equal to $L/2$, and the first one is $L(1/4 + 1/2\pi)$. Therefore, $P = [(2/L)^{3/2}]^2(L/2)^2[L(1/4 + 1/2\pi)] = 1/2 + 1/\pi = 0.818$.

(b) The state is (2,1,2). The only difference from part (a) is the x integral, which is

$$\int_{L/4}^{3L/4}\sin^2\frac{2\pi x}{L}dx = L/4.$$

Therefore $P = (2/L)^3(L/2)^2(L/4) = 0.500$.

(c) The state is (3,2,3). Only the x integral is different from parts (a) and (b).

$$\int_{L/4}^{3L/4}\sin^2\frac{3\pi x}{L}dx = \frac{L}{4} - \frac{L}{6\pi} = L\left(\frac{1}{4} - \frac{1}{6\pi}\right).$$

$P = (2/L)^3(L/2)^2L(1/4 - 1/6\pi) = 0.394$.

(d) The state is (4,1,1). Use the same procedure. In this case, the x integral gives $L/4$, so the probability is $P = (2/L)^3(L/2)^2(L/4) = 0.500$.

EVALUATE: Note that the probability is 0.500 whenever n_X is an even integer. Also note that even though the region contains half the volume of the cube, the probability of finding a particle there is not necessarily 0.500.

VP41.1.3. **IDENTIFY:** This problem involves a particle in a three-dimensional cubical box.
SET UP: Eq. (41.15) gives the wave function of the particle, and the square of the wave function is the probability density. We want the probability of finding the particle in the region $0 \le x \le L/4$, $0 \le y \le L/4$. Use the same approach as in the previous two problems.
EXECUTE: **(a)** The state is (1,1,1). We integrate using results from Example 41.1. $C = (2/L)^{3/2}$.

$$P = \left(\frac{2}{L}\right)^3 \int_0^{L/4} \sin^2 \frac{\pi x}{L} dx \int_0^{L/4} \sin^2 \frac{\pi y}{L} dy \int_0^{L} \sin^2 \frac{\pi z}{L} dz.$$

The z integral is equal to $L/2$. The y and z integrals are each equal to $L(1/8 - 1/4\pi)$. Therefore

$$P = (2/L)^3(L)[L(1/8 - 1/4\pi)]^2 = 8.25 \times 10^{-3}.$$

(b) The state is (2,1,2). Use the previous results and those of example 41.1. Doing so, we find that the x integral is $L/8$, the y integral is $L(1/8 - 1/4\pi)$, and the z integral is $L/2$. The probability is

$$P = (2/L)^3(L/8)[L(1/8 - 1/4\pi)](L/2) = 0.0227.$$

(c) The state is (3,2,3). The x integral is $L(1/8 + 1/12\pi)$, the y integral is $L/8$, the z integral is $L/2$, so $P = (2/L)^3[L(1/8 + 1/12\pi)](L/8)(L/2) = 0.0758$.
(d) The state is (4,1,1). x integral is $L/8$, y integral is $L(1/8 - 1/4\pi)$, z integral is $L/2$, so $P = 0.0227$.
EVALUATE: Note that $P_{4,1,1}$ is the same as $P_{2,1,2}$. Also note that even though the region contains 6.25% of the volume of the cube, the probability of finding a particle there is not necessarily 0.0625.

VP41.1.4. **IDENTIFY:** This problem involves a particle in a three-dimensional cubical box.
SET UP: Eq. (41.15) gives the wave function of the particle, and the square of the wave function is the probability density.
EXECUTE: **(a)** We want $V_{\text{inside}}/V_{\text{box}}$. $V_{\text{box}} = L^3$ and $V_{\text{inside}} = (L/2)^3 = L^3/8$. Dividing the volumes gives $V_{\text{inside}}/V_{\text{box}} = (L^3/8)/L^3 = 1/8 = 0.125$.
(b) We want the probability that the particle is in this region. We use the wave functions in Eq. (41.15), square them and integrate to get the probability as in the previous problems. All the integrals are of the same form as the x integral in problem VP41.1.2(a), so each integral gives the factor $L(1/4 + 1/2\pi)$. The probability is $P = (2/L)^3[L(1/4 + 1/2\pi)]^3 = 0.548$.
EVALUATE: Note that the probability of finding the particle in the given volume is not necessarily the same as the percent that volume is of the total volume of the box. We have see the same thing in previous problems.

VP41.4.1. **IDENTIFY:** We are looking at the possible states of the hydrogen atom with $n = 3$.
SET UP: $l = 0, 1, 2, \ldots, n - 1$ and $m_l = 0, \pm 1, \pm 2, \ldots, \pm l$. $L = \sqrt{l(l+1)}\,\hbar$. $L_z = m_l \hbar$, $\cos\theta_L = L_z/L$.
EXECUTE: **(a)** $l = 0, 1, \ldots, 5$ and $m_l = 0, \pm 1, \pm 2, \ldots, \pm 5$. The possible states are:
$l = 0$, $m_l = 0$: 1 state
$l = 1$, $m_l = 0, \pm 1$: 3 states
$l = 2$, $m_l = 0, \pm 1, \pm 2$: 5 states
$l = 3$, $m_l = 0, \pm 1, \pm 2, \pm 3$: 7 states
$l = 4$, $m_l = 0, \pm 1, \pm 2, \pm 3, \pm 4$: 9 states
$l = 5$, $m_l = 0, \pm 1, \pm 2, \pm 3, \pm 4, \pm 5$: 11 states
The total is 36 states.
(b) $l_{\max} = 5$, so $L_{\max} = \sqrt{5(5+1)}\,\hbar = \sqrt{30}\,\hbar$.
(c) $L_z = m_l \hbar$, so the maximum L_z is $5\hbar$.
EVALUATE: As n increases, the number of possible states increases rapidly.

VP41.4.2. **IDENTIFY:** We are looking at the possible states of the hydrogen atom with $n = 6$.

SET UP: $l = 0, 1, 2, \ldots, n - 1$ and $m_l = 0, \pm 1, \pm 2, \ldots, \pm l$. $L = \sqrt{l(l+1)}\,\hbar$. $L_z = m_l\hbar$.

EXECUTE: **(a)** Using the restrictions on l and m_l gives

$l = 0$, $m_l = 0$

$l = 1$, $m_l = 0, \pm 1$

$l = 2$, $m_l = 0, \pm 1, \pm 2$

So the (l, m_l) states are (0, 0), (1, –1), (1, 0), (1, 1), (2, –2), (2, –1), (2, 0), (2, 1), (2, 2).

(b) Using $\cos\theta_L = L_z/L$, we see that the angle between the orbital angular momentum and the *negative* z-axis will be a minimum when θ_L is closest to π, so the cosine should be closest to –1.

$$\cos\theta_L = L_z/L = \frac{m_l\hbar}{\sqrt{l(l+1)}\hbar} = \frac{m_l}{\sqrt{l(l+1)}}.$$

So for $m_l = -2$ and $l = 2$, we get $\cos\theta_L = -2/\sqrt{6}$, which gives $\theta_L = 144.7°$. Therefore the angle with the $-z$-axis is 180° – 144.7° = 35.3°. This is for the state $l = 2$, $m_l = -2$.

EVALUATE: The greatest angle that the angular momentum makes with the $+z$-axis is 144.7°.

VP41.4.3. **IDENTIFY:** We are looking at transition energy in the hydrogen atom.

SET UP: $E_n = -(13.60\text{ eV})/n^2$. The energy of a shell depends on n. The photon energy is equal to the energy lost by an electron due to its transition to a lower energy level.

EXECUTE: **(a)** $n = 3 \rightarrow n = 2$. $\Delta E = (13.6\text{ eV})(1/2^2 - 1/3^2) = 1.89$ eV.

(b) $n = 4 \rightarrow n = 2$. $\Delta E = (13.6\text{ eV})(1/2^2 - 1/4^2) = 2.55$ eV.

(c) $n = 2 \rightarrow n = 1$. $\Delta E = (13.6\text{ eV})(1/1^2 - 1/2^2) = 10.2$ eV.

EVALUATE: Note that the energy difference between adjacent shells is not the same but depends on the value of n.

VP41.4.4. **IDENTIFY:** We are investigating the properties of the hydrogen wave function.

SET UP: The probability density is the square of the wave function. We want the probability that the electron will be found within each given region using the given wave function.

$$P = \int |\psi|^2\, dV = \int \frac{1}{\pi a^3} e^{-2r/a}\, 4\pi r^2\, dr = -\frac{4}{a^3}\left(\frac{ar^2}{2} + \frac{a^2 r}{2} + \frac{a^3}{4}\right)e^{-2r/a}.$$

EXECUTE: **(a)** $0 \le r \le 2a$. Evaluating the expression above for the limits of the integral gives

$$P = -\frac{4}{a^3}\left[\left(2a^3 + a^3 + \frac{a^3}{4}\right)e^{-4} - \frac{a^3}{4}\right] = -\left(\frac{13}{e^4} - 1\right) = 0.762.$$

(b) $a \le r \le 3a$. Evaluating as in part (a) for the new limits gives $P = 0.615$.

(c) $r \ge 4a$. In this case, the upper limit is infinity. Evaluating as before gives $P = 0.0138$.

EVALUATE: Our results are consistent with Figure 41.8 in the textbook for a 1s electron in hydrogen. From the graph for a 1s electron, we see that the probability distribution for $P(r)$ is a maximum at $r = a$. The range in part (a) includes that value, so the probability for that range is greater than for the others that do not include it.

VP41.8.1. **IDENTIFY:** This problem involves the Zeeman effect in which an external magnetic field affects the energy levels.

SET UP: The following conditions hold:

$$U = -\mu_z B,\ \mu_z = -(2.00232)\frac{e}{2m}S_z,\ \ S_z = \pm\frac{\hbar}{2}.$$

EXECUTE: **(a)** We want the energy differenc. Combing these conditions gives

$$\Delta U = (2.00232)\frac{eB}{2m}\Delta S_z = (2.00232)\frac{eB}{2m}\left[\frac{\hbar}{2} - \left(-\frac{\hbar}{2}\right)\right] = (2.00232)\mu_B B.$$

Using $B = 3.14$ T and $\mu_B = 5.788 \times 10^{-5}$ eV/T gives $\Delta U = 3.64 \times 10^{-4}$ eV.

(b) We want to know which state has greater energy.

$$U = -\mu_z B = -(-2.00232)\frac{e}{2m}S_z B = +(2.00232)\frac{eB}{2m}S_z, \text{ so } S_z = +\frac{\hbar}{2} \text{ has greater energy.}$$

EVALUATE: The *magnitude* of the energy is the same for either of the S_z states.

VP41.8.2. **IDENTIFY:** We are looking at the effect of an external magnetic field on an atom.

SET UP: The energy of the radiation must be equal to the energy difference between the two spin states of the outermost electron. The following conditions hold:

$$U = -\mu_z B,\ \mu_z = -(2.00232)\frac{e}{2m}S_z,\ S_z = \pm\frac{\hbar}{2}$$

EXECUTE: As we saw in problem VP41.8.1(a).

$$\Delta U = (2.00232)\frac{eB}{2m}\Delta S_z = (2.00232)\frac{eB}{2m}\left[\frac{\hbar}{2} - \left(-\frac{\hbar}{2}\right)\right] = (2.00232)\mu_B B.$$

The radiation energy hf must therefore be $hf = (2.00232)\mu_B B$. Using $B = 2.36$ T and solving for f gives $f = 6.61 \times 10^{10}$ Hz. The wavelength is $\lambda = c/f = 4.53$ mm.

EVALUATE: The energy difference between the two spin states is very small, so the wavelength is much longer than that of visible light.

VP41.8.3. **IDENTIFY:** This problem deals with the effect of a magnetic field on the energy levels of an atom.

SET UP: We know the energy of a photon and from the two previous problems we know the energy difference due to the magnetic field.

$$\Delta U = (2.00232)\mu_B B,\ E = hc/\lambda$$

EXECUTE: **(a)** We want the energy difference between the two $4p$ levels.

$$\Delta E = \frac{hc}{\lambda_1} - \frac{hc}{\lambda_2} = \frac{hc(\lambda_2 - \lambda_1)}{\lambda_1 \lambda_2}.$$

Using the given wavelengths gives $\Delta E = 7.16 \times 10^{-3}$ eV.

(b) We want the magnetic field. We use the energy difference from part (a) and solve for B.

$\Delta U = (2.00232)\mu_B B$

$$B = 61.8 \text{ T}.$$

EVALUATE: This is a *very* strong magnetic field.

VP41.8.4. **IDENTIFY:** This problem involves the effect of spin and angular momentum on the energy of the hydrogen atom.

SET UP: Eq. (41.41) gives the energy levels, where $j = |l \pm \frac{1}{2}|$.

EXECUTE: **(a)** Use Eq. (41.41) to calculate the energy levels.

$$E_{3,3/2} = -\frac{13.60 \text{ eV}}{3^2}\left[1 + \frac{\alpha^2}{3^2}\left(\frac{3}{3/2 + 1/2} - \frac{3}{4}\right)\right] = -1.511 \text{ eV}\left(1 + \frac{\alpha^2}{12}\right).$$

$$E_{3,1/2} = -1.511 \text{ eV}\left(1 + \frac{\alpha^2}{4}\right)$$

(b) $$E_{3,3/2} - E_{3,1/2} = -1.511 \text{ eV}\left[\left(1 + \frac{\alpha^2}{12}\right) - \left(1 + \frac{\alpha^2}{4}\right)\right] = (-1.511\alpha^2)\left(\frac{1}{12} - \frac{1}{4}\right) = 1.34 \times 10^{-5} \text{ eV}.$$

The difference is positive, so the $j = 3/2$ state has higher energy.

(c) We want the difference in wavelengths. Use the answer from part (b) and the approach of Example 41.8.

As in that example, the difference in the wavelengths is

$$\Delta\lambda = -\frac{\lambda}{E_{\text{photon}}}\Delta E_{\text{photon}}.$$

The *difference* in the energy between the $j = 3/2$ and $j = 1/2$ levels of the $n = 3$ shell is *very small* compared to the energy of that shell. Therefore the energy of the photon is essentially $E_3 - E_2$.

$$E_{\text{photon}} = E_3 - E_2 = -\frac{13.60\text{ eV}}{3^2} - \left(-\frac{13.60\text{ eV}}{2^2}\right) = 1.8890\text{ eV}.$$

The wavelength of this photon is

$$\lambda = hc/E_{\text{photon}} = hc/(1.8890\text{ eV}) = 6.565\times10^{-7}\text{ m}.$$

The difference in the wavelengths is therefore

$$\Delta\lambda = -\frac{\lambda}{E_{\text{photon}}}\Delta E_{\text{photon}} = -\frac{4.136\times10^{-15}\text{ eV}\cdot\text{s}}{1.8890\text{ eV}}(1.34\times10^{-5}\text{ eV}) = -4.66\times10^{-12}\text{ m} = -4.66\times10^{-3}\text{ nm}.$$

$\lambda_1 - \lambda_2$ is negative, so $\lambda_2 > \lambda_1$ with λ_2 being for the $j = ½$ initial state.

EVALUATE: As a check, you could also calculate the energy differences using Eq. (41.41) and calculate the wavelength differences from those results. But the algebra gets a bit tedious.

41.1. **IDENTIFY:** For a particle in a cubical box, different values of $n_X, n_Y,$ and n_Z can give the same energy.

SET UP: $E_{n_X, n_Y, n_Z} = \dfrac{(n_X^2 + n_Y^2 + n_Z^2)\pi^2\hbar^2}{2mL^2}.$

EXECUTE: **(a)** $n_X^2 + n_Y^2 + n_Z^2 = 3.$ This only occurs for $n_X = 1, n_Y = 1, n_Z = 1,$ so the degeneracy is 1.

(b) $n_X^2 + n_Y^2 + n_Z^2 = 9.$ This occurs for $n_X = 2, n_Y = 2, n_Z = 1,$ for $n_X = 1, n_Y = 2, n_Z = 2,$ and for $n_X = 2, n_Y = 1, n_Z = 2,$ so the degeneracy is 3.

EVALUATE: In the second case, three different states all have the same energy.

41.2. **IDENTIFY:** Use an electron in a cubical box to model the hydrogen atom.

SET UP: $E_{1,1,1} = \dfrac{3\pi^2\hbar^2}{2mL^2}.$ $E_{2,1,1} = \dfrac{6\pi^2\hbar^2}{2mL^2}.$ $\Delta E = \dfrac{3\pi^2\hbar^2}{2mL^2}.$ $L^3 = \dfrac{4}{3}\pi a^3.$

$$L = \left(\frac{4\pi}{3}\right)^{1/3} a = 8.527\times10^{-11}\text{ m}.$$

EXECUTE: $\Delta E = \dfrac{3\pi^2(1.055\times10^{-34}\text{ J}\cdot\text{s})^2}{2(9.109\times10^{-31}\text{ kg})(8.53\times10^{-11}\text{ m})^2} = 2.49\times10^{-17}\text{ J} = 155\text{ eV}.$ In the Bohr model, $E_n = -\dfrac{13.6\text{ eV}}{n^2}.$ The energy separation between the $n = 2$ and $n = 1$ levels is

$$\Delta E_{\text{Bohr}} = (13.6\text{ eV})\left(\frac{1}{1^2} - \frac{1}{2^2}\right) = \frac{3}{4}(13.6\text{ eV}) = 10.2\text{ eV}.$$

EVALUATE: A particle in a box is not a good model for a hydrogen atom.

41.3. **IDENTIFY:** The energy of the photon is equal to the energy difference between the states. We can use this energy to calculate its wavelength.

SET UP: $E_{1,1,1} = \dfrac{3\pi^2\hbar^2}{2mL^2}.$ $E_{2,2,1} = \dfrac{9\pi^2\hbar^2}{2mL^2}.$ $\Delta E = \dfrac{3\pi^2\hbar^2}{mL^2}.$ $\Delta E = \dfrac{hc}{\lambda}.$

EXECUTE: $\Delta E = \dfrac{3\pi^2(1.055\times10^{-34}\text{ J}\cdot\text{s})^2}{(9.109\times10^{-31}\text{ kg})(8.00\times10^{-11}\text{ m})^2} = 5.653\times10^{-17}\text{ J}.$ $\Delta E = \dfrac{hc}{\lambda}$ gives

$$\lambda = \frac{hc}{\Delta E} = \frac{(6.626\times10^{-34}\text{ J}\cdot\text{s})(2.998\times10^{8}\text{ m/s})}{5.653\times10^{-17}\text{ J}} = 3.51\times10^{-9}\text{ m} = 3.51\text{ nm}.$$

EVALUATE: This wavelength is much shorter than that of visible light.

41.4. IDENTIFY: Use the probability function for a particle in a three-dimensional box to find the points where it is a maximum.

(a) SET UP: $n_X = 1, n_Y = 1, n_Z = 1.$ $|\psi|^2 = \left(\frac{L}{2}\right)^3 \left(\sin^2 \frac{\pi x}{L}\right)\left(\sin^2 \frac{\pi y}{L}\right)\left(\sin^2 \frac{\pi z}{L}\right).$

EXECUTE: $|\psi|^2$ is maximum where $\sin\frac{\pi x}{L} = \pm 1,$ $\sin\frac{\pi y}{L} = \pm 1,$ and $\sin\frac{\pi z}{L} = \pm 1.$ $\frac{\pi x}{L} = \frac{\pi}{2}$ and $x = \frac{L}{2}.$ The next larger value is $\frac{\pi x}{L} = \frac{3\pi}{2}$ and $x = \frac{3L}{2},$ but this is outside the box. Similar results obtain for y and z, so $|\psi|^2$ is maximum at the point $x = y = z = L/2.$ This point is at the center of the box.

(b) SET UP: $n_X = 2, n_Y = 2, n_Z = 1.$ $|\psi|^2 = \left(\frac{L}{2}\right)^3 \left(\sin^2 \frac{2\pi x}{L}\right)\left(\sin^2 \frac{2\pi y}{L}\right)\left(\sin^2 \frac{\pi z}{L}\right).$

EXECUTE: $|\psi|^2$ is maximum where $\sin\frac{2\pi x}{L} = \pm 1,$ $\sin\frac{2\pi y}{L} = \pm 1,$ and $\sin\frac{\pi z}{L} = \pm 1.$ $\frac{2\pi x}{L} = \frac{\pi}{2}$ and $x = \frac{L}{4}.$ $\frac{2\pi x}{L} = \frac{3\pi}{2}$ and $x = \frac{3L}{4}.$ Similarly, $y = \frac{L}{4}$ and $\frac{3L}{4}.$ As in part (a), $z = \frac{L}{2}.$ $|\psi|^2$ is a maximum at the four points $\left(\frac{L}{4}, \frac{L}{4}, \frac{L}{2}\right),$ $\left(\frac{L}{4}, \frac{3L}{4}, \frac{L}{2}\right),$ $\left(\frac{3L}{4}, \frac{L}{4}, \frac{L}{2}\right),$ and $\left(\frac{3L}{4}, \frac{3L}{4}, \frac{L}{2}\right).$

EVALUATE: The points are located symmetrically relative to the center of the box.

41.5. IDENTIFY: This problem is about an electron in a three-dimensional cubical box.

SET UP: The energy levels are given by Eq. (41.16). In the ground state, all three quantum numbers are equal to 1. In the second excited state, two are equal to 2 and one is equal to 1. Therefore the energy levels are $E_1 = \frac{3\pi^2\hbar^2}{2mL^2}$ and $E_2 = \frac{9\pi^2\hbar^2}{2mL^2}.$ The photon energy is $E = hc/\lambda.$ We want L.

EXECUTE: The energy of the photon is equal to the energy difference between the two states.

$$\Delta E = (9-3)\frac{\pi^2\hbar^2}{2mL^2} = \frac{hc}{\lambda}.\ L = \sqrt{\frac{3h\lambda}{4mc}} = \sqrt{\frac{3h(8.00\text{ nm})}{4mc}} = 0.121\text{ nm}.$$

EVALUATE: The diameter of a Bohr-model hydrogen atom is about 0.11 nm, so this box is around that size.

41.6. IDENTIFY: A proton is in a cubical box approximately the size of the nucleus.

SET UP: $E_{1,1,1} = \frac{3\pi^2\hbar^2}{2mL^2}.$ $E_{2,1,1} = \frac{6\pi^2\hbar^2}{2mL^2}.$ $\Delta E = \frac{3\pi^2\hbar^2}{2mL^2}.$

EXECUTE: $\Delta E = \frac{3\pi^2(1.055\times10^{-34}\text{ J}\cdot\text{s})^2}{2(1.673\times10^{-27}\text{ kg})(1.00\times10^{-14}\text{ m})^2} = 9.85\times10^{-13}\text{ J} = 6.15\text{ MeV}.$

EVALUATE: This energy difference is much greater than the energy differences involving orbital electrons.

41.7. IDENTIFY: This problem is about an electron in a three-dimensional cubical box.

SET UP: The probability density is the square of the wave function, and Eq. (41.15) gives the wave function. We want the planes for which the probability density is zero, which is where the wave function is zero.

EXECUTE: x-axis: $n_X = 3$, so $3\pi x/L = \pi, 2\pi$. This gives $x = L/3$, $x = 2L/3$.

y-axis: $n_Y = 2$, so $2\pi y/L = \pi$. This gives $y = L/2$.

z-axis: $n_Z = 1$, so $\pi z/L = \pi$. This gives $z = L$, so there are no z-planes within the box.

EVALUATE: For the z-axis the probability is zero only at the walls of the box.

41.8. **IDENTIFY:** We are comparing the quantum mechanical description of the hydrogen atom with the Bohr model.

SET UP: Quantum model: $L = \sqrt{l(l+1)}\,\hbar$, Bohr model: $L = n\hbar$.

EXECUTE: **(a)** $n = 3$. Quantum model: The largest l is $n - 1 = 2$.

$L = \sqrt{l(l+1)}\,\hbar = \sqrt{29(29+1)}\,\hbar = 29.5\hbar$.

Bohr model: $L = n\hbar = 30\hbar$.

Percent difference = (3.00 – 2.45)/3.00 = 18%.

(b) $n = 30$. $l = n - 1 = 29$. Quantum model: $L = \sqrt{l(l+1)}\,\hbar = \sqrt{29(29+1)}\hbar = 29.5\hbar$.

Bohr model: $L = n\hbar = 30\hbar$.

Percent difference = (30 – 29.5)/30 = 1.7%.

EVALUATE: For higher states, the results for quantum mechanical and Bohr models get closer together.

41.9. **IDENTIFY:** The possible values of the angular momentum are limited by the value of n.

SET UP: For the N shell $n = 4$, $0 \le l \le n-1$, $|m| \le l$, $m_s = \pm\frac{1}{2}$.

EXECUTE: **(a)** The smallest l is $l = 0$. $L = \sqrt{l(l+1)}\hbar$, so $L_{\text{min}} = 0$.

(b) The largest l is $n-1 = 3$, so $L_{\text{max}} = \sqrt{3(4)}\hbar = 2\sqrt{3}\hbar = 3.65\times10^{-34}\ \text{kg}\cdot\text{m}^2/\text{s}$.

(c) Let the chosen direction be the z-axis. The largest m is $m = l = 3$.

$$L_{z,\text{max}} = m\hbar = 3\hbar = 3.16\times10^{-34}\ \text{kg}\cdot\text{m}^2/\text{s}.$$

(d) $S_z = \pm\frac{1}{2}\hbar$. The maximum value is $S_z = \hbar/2 = 5.27\times10^{-35}\ \text{kg}\cdot\text{m}^2/\text{s}$.

(e) $\dfrac{S_z}{L_z} = \dfrac{\frac{1}{2}\hbar}{3\hbar} = \dfrac{1}{6}$.

EVALUATE: The orbital and spin angular momenta are of comparable sizes.

41.10. **IDENTIFY** and **SET UP:** $L = \sqrt{l(l+1)}\hbar$. $L_z = m_l\hbar$. $l = 0, 1, 2, \ldots, n-1$. $m_l = 0, \pm1, \pm2, \ldots, \pm l$.

$\cos\theta = L_z/L$.

EXECUTE: **(a)** Use $L = \sqrt{l(l+1)}\hbar$.

$\underline{l=0}$: $L = 0$, $L_z = 0$.

$\underline{l=1}$: $L = \sqrt{2}\hbar$, $L_z = \hbar, 0, -\hbar$.

$\underline{l=2}$: $L = \sqrt{6}\hbar$, $L_z = 2\hbar,\ \hbar,\ 0,\ -\hbar,\ -2\hbar$.

$\underline{l=3}$: $L = 2\sqrt{3}\hbar$, $L_z = 3\hbar,\ 2\hbar,\ \hbar,\ 0,\ -\hbar,\ -2\hbar,\ -3\hbar$.

$\underline{l=4}$: $L = 2\sqrt{5}\hbar$, $L_z = 4\hbar,\ 3\hbar,\ 2\hbar,\ \hbar,\ 0,\ -\hbar,\ -2\hbar,\ -3\hbar,\ -4\hbar$.

(b) Use $\cos\theta = L_z/L$.

$\underline{L=0}$: θ is not defined.

$\underline{L=\sqrt{2}\hbar}$: 45.0°, 90.0°, 135.0°.

$\underline{L=\sqrt{6}\hbar}$: 35.3°, 65.9°, 90.0°, 114.1°, 144.7°.

$\underline{L=2\sqrt{3}\hbar}$: 30.0°, 54.7°, 73.2°, 90.0°, 106.8°, 125.3°, 150.0°.

$\underline{L=2\sqrt{5}\hbar}$: 26.6°, 47.9°, 63.4°, 77.1°, 90.0°, 102.9°, 116.6°, 132.1°, 153.4°.

(c) The minimum angle is 26.6° and occurs for $l = 4$, $m_l = +4$. The maximum angle is 153.4° and occurs for $l = 4$, $m_l = -4$.

EVALUATE: There is no state where $\vec{L}$ is totally aligned along the z-axis.

41.11. **IDENTIFY** and **SET UP:** The magnitude of the orbital angular momentum L is related to the quantum number l by Eq. (41.22): $L=\sqrt{l(l+1)}\hbar$, $l=0, 1, 2,\dots$

EXECUTE: $l(l+1)=\left(\dfrac{L}{\hbar}\right)^2=\left(\dfrac{4.716\times10^{-34}\ \text{kg}\cdot\text{m}^2/\text{s}}{1.055\times10^{-34}\ \text{J}\cdot\text{s}}\right)^2=20.$

And then $l(l+1)=20$ gives that $l=4$.

EVALUATE: l must be integer.

41.12. **IDENTIFY** and **SET UP:** $L=\sqrt{l(l+1)}\hbar.$ $L_z=m_l\hbar.$ $m_l=0, \pm1, \pm2, \dots, \pm l.$ $\cos\theta=L_z/L.$

EXECUTE: **(a)** $(m_l)_{\text{max}}=2$, so $(L_z)_{\text{max}}=2\hbar.$

(b) $L=\sqrt{l(l+1)}\hbar=\sqrt{6}\hbar=2.45\hbar.$ L is larger than $(L_z)_{\text{max}}$.

(c) The angle is $\arccos\left(\dfrac{L_z}{L}\right)=\arccos\left(\dfrac{m_l}{\sqrt{6}}\right)$, and the angles are, for $m_l=-2$ to $m_l=+2$ are:

$144.7°,\ 114.1°,\ 90.0°,\ 65.9°, 35.3°.$

EVALUATE: The minimum angle for a given l is for $m_l=l.$ The angle corresponding to $m_l=l$ will always be smaller for larger l.

41.13. **IDENTIFY** and **SET UP:** The smallest nonzero angle for a given l occurs for $m_l=+l.$ $L=\sqrt{l(l+1)}\hbar$ and $L_z=m_l\hbar$ where $m_l=0, \pm1, \pm2, \dots,\pm l.$ $\cos\theta=L_z/L.$

EXECUTE: In this case $\theta=26.6°$, so $\cos 26.6^\circ=\dfrac{l}{\sqrt{l(l+1)}}$. Squaring gives $l(l+1)\cos^2(26.6^\circ)=l^2.$

Solving for l gives $l=\dfrac{\cos^2(26.6^\circ)}{1-\cos^2(26.6^\circ)}=4.$

EVALUATE: For $l=4$ we see that the angle between the angular momentum vector and the positive z-axis ranges from $26.6°\ (m_l=+l)$ to $180°-26.6°=153.4°(m_l=-l).$

41.14. **IDENTIFY** and **SET UP:** $L=\sqrt{l(l+1)}\hbar.$ $\cos\theta_L=L_z/L.$ We know that $L_z=2\hbar$ in this case, and $\theta_L=63.4°.$ For any n, l can have the values $l=0, 1, 2, \dots, n-1$.

EXECUTE: **(a)** First find L: $L=\dfrac{L_z}{\cos\theta_L}=\dfrac{2\hbar}{\cos(63.4°)}=4.467\hbar.$

Now solve for l: $L=\sqrt{l(l+1)}\hbar=4.467\,\hbar\ \rightarrow\ l(l+1)=(4.467)^2\approx 20=4(4+1)$, so $l=4$.

(b) The maximum that l can be is $n-1$, so $n-1\geq l_{\max}$, which means that $n\geq l_{\max}+1$. In this case, we know that $l=4$, so $n\geq 5$, so the smallest that n could be is 5.

EVALUATE: Any $n>5$ is also possible.

41.15. **IDENTIFY:** This problem deals with a hydrogen atom in the seventh excited level. For the seventh *excited* level, $n=8$.

SET UP and **EXECUTE:** **(a)** We want the energy. $E_n=-(13.6\text{ eV})/n^2=-(13..6\text{ eV})/8^2=-0.213$ eV.

(b) We want $L_{\max}$. $L=\sqrt{l(l+1)}\hbar$ and $l_{\max}=n-1=7.$ $L_{\max}=\sqrt{7(7+1)}\ \hbar=7.48\hbar.$

(c) We want the largest possible angle. $\cos\theta_L=L_z/L.$ $L_z=m_l\hbar$, and $m_l=0, \pm1, \dots, \pm l$. The angle will be greatest when L_z is most negative, which in this case is when $m_l=-7$, so $l=7$. Therefore $\cos\theta_L=-7/7.48$, which gives $\theta_L=159°$.

EVALUATE: There are many other possible values for θ_L but the value we found is the largest this angle can be.

41.16. IDENTIFY: $l = 0, 1, 2, \ldots, n-1.\;\; m_l = 0, \pm 1, \pm 2, \ldots, \pm l.$

SET UP: $E_n = -\dfrac{13.60\text{ eV}}{n^2}.$

EXECUTE: Since $n = 4$, l can have the values 0, 1, 2, and 3. For each value of l, m_l can range from $-l$ to $+l$. Therefore the (l, m_l) combinations are $(0, 0), (1, 0),\; (1, \pm 1), (2, 0),\; (2, \pm 1), (2, \pm 2), (3, 0),$ $(3, \pm 1), (3, \pm 2),$ and $(3, \pm 3),$ a total of 16 combinations.

(b) Each state has the same energy because n is the same for all of them, so

$$E = -\frac{13.60\text{ eV}}{4^2} = -0.8500\text{ eV}.$$

EVALUATE: The number of l, m_l combinations is n^2. The energy depends only on n, so is the same for all l, m_l states for a given n.

41.17. IDENTIFY: For the 5g state, $l = 4$, which limits the other quantum numbers.

SET UP: $m_l = 0, \pm 1, \pm 2, \ldots, \pm l.$ g means $l = 4$. $\cos\theta = L_z/L$, with $L = \sqrt{l(l+1)}\,\hbar$ and $L_z = m_l\hbar.$

EXECUTE: **(a)** There are eighteen 5g states: $m_l = 0, \pm 1, \pm 2, \pm 3, \pm 4$, with $m_s = \pm\frac{1}{2}$ for each.

(b) The largest θ is for the most negative m_l. $L = 2\sqrt{5}\hbar.$ The most negative L_z is $L_z = -4\hbar.$

$$\cos\theta = \frac{-4\hbar}{2\sqrt{5}\hbar} \text{ and } \theta = 153.4°.$$

(c) The smallest θ is for the largest positive m_l, which is $m_l = +4$. $\cos\theta = \dfrac{4\hbar}{2\sqrt{5}\hbar}$ and $\theta = 26.6°.$

EVALUATE: The minimum angle between $\vec{L}$ and the z-axis is for $m_l = +l$ and for that m_l,

$\cos\theta = \dfrac{l}{\sqrt{l(l+1)}}.$

41.18. IDENTIFY: The probability is $P = \int_0^{a/2} |\psi_{1s}|^2\, 4\pi r^2 dr.$

SET UP: Use the expression for the integral given in Example 41.4.

EXECUTE: **(a)** $P = \dfrac{4}{a^3}\left[\left(-\dfrac{ar^2}{2} - \dfrac{a^2 r}{2} - \dfrac{a^3}{4}\right)e^{-2r/a}\right]_0^{a/2} = 1 - \dfrac{5e^{-1}}{2} = 0.0803.$

(b) Example 41.4 calculates the probability that the electron will be found at a distance less than a from the nucleus. The difference in the probabilities is $(1 - 5e^{-2}) - (1 - (5/2)e^{-1}) = (5/2)(e^{-1} - 2e^{-2}) = 0.243.$

EVALUATE: The probability for distances from $a/2$ to a is about three times the probability for distances between 0 and $a/2$. This agrees with Figure 41.8 in the textbook; $P(r)$ is maximum for $r = a$.

41.19. IDENTIFY: Require that $\Phi(\phi) = \Phi(\phi + 2\pi).$

SET UP: $e^{i(x_1 + x_2)} = e^{ix_1}e^{ix_2}.$

EXECUTE: $\Phi(\phi + 2\pi) = e^{im_l(\phi + 2\pi)} = e^{im_l\phi}e^{im_l 2\pi}.$ $e^{im_l 2\pi} = \cos(m_l 2\pi) + i\sin(m_l 2\pi).$ $e^{im_l 2\pi} = 1$ if m_l is an integer.

EVALUATE: If, for example, $m_l = \frac{1}{2}$, $e^{im_l 2\pi} = e^{i\pi} = \cos(\pi) + i\sin(\pi) = -1$ and $\Phi(\phi) = -\Phi(\phi + 2\pi).$ But if $m_l = 1$, $e^{im_l 2\pi} = e^{i2\pi} = \cos(2\pi) + i\sin(2\pi) = +1$ and $\Phi(\phi) = \Phi(\phi + 2\pi)$, as required.

41.20. **IDENTIFY:** This problem is about the probability distribution for hydrogen.
SET UP: Refer to the graphs in Figure 41.8 in the textbook, $a = 5.29 \times 10^{-11}$ m.
EXECUTE: **(a)** $r/a = (0.476 \text{ nm})/a = 9.00$. From the bottom graph in Figure 41.8 we see that the 3*d* curve peaks at approximately $r/a = 9.00$ and has only one peak, so this must be the state.
(b) Using the same graph as in (a), we see that the 4*f* graph peaks at $r/a \approx 16$, so $r \approx 16a = 0.85$ nm.
EVALUATE: Note that the 4*f* state peaks after the 3*d* state, but *before* the second peak of the 4*d* state.

41.21. **IDENTIFY:** Apply $\Delta U = \mu_B B$.
SET UP: For a 3*p* state, $l = 1$ and $m_l = 0, \pm 1$.
EXECUTE: **(a)** $B = \dfrac{U}{\mu_B} = \dfrac{(2.71\times10^{-5} \text{ eV})}{(5.79\times10^{-5} \text{ eV/T})} = 0.468 \text{ T}.$
(b) Three: $m_l = 0, \pm 1$.
EVALUATE: The $m_l = +1$ level will be highest in energy and the $m_l = -1$ level will be lowest. The $m_l = 0$ level is unaffected by the magnetic field.

41.22. **IDENTIFY:** Apply $\Delta E = \mu_B B$.
SET UP: $\mu_B = 5.788\times10^{-5}$ eV/T.
EXECUTE: **(a)** $\Delta E = \mu_B B = (5.79\times10^{-5} \text{ eV/T})(0.800 \text{ T}) = 4.63\times10^{-5} \text{ eV}.$
(b) $m_l = -2$ the lowest possible value of m_l.
(c) The energy level diagram is sketched in Figure 41.22.

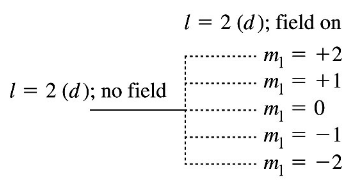

Figure 41.22

EVALUATE: The splitting between m_l levels is independent of the *n* values for the state. The splitting is much less than the energy difference between the $n = 3$ level and the $n = 1$ level.

41.23. **IDENTIFY** and **SET UP:** The interaction energy between an external magnetic field and the orbital angular momentum of the atom is given by $U = m_l \mu_B B$. The energy depends on m_l with the most negative m_l value having the lowest energy.
EXECUTE: **(a)** For the 5*g* level, $l = 4$ and there are $2l + 1 = 9$ different m_l states. The 5*g* level is split into 9 levels by the magnetic field.
(b) Each m_l level is shifted in energy an amount given by $U = m_l \mu_B B$. Adjacent levels differ in m_l by one, so $\Delta U = \mu_B B$.

$$\mu_B = \frac{e\hbar}{2m} = \frac{(1.602\times10^{-19} \text{ C})(1.055\times10^{-34} \text{ J}\cdot\text{s})}{2(9.109\times10^{-31} \text{ kg})} = 9.277\times10^{-24} \text{ A}\cdot\text{m}^2.$$

$\Delta U = \mu_B B = (9.277\times10^{-24} \text{ A/m}^2)(0.600 \text{ T}) = 5.566\times10^{-24} \text{ J}(1 \text{ eV}/1.602\times10^{-19} \text{ J}) = 3.47\times10^{-5} \text{ eV}.$
(c) The level of highest energy is for the largest m_l, which is $m_l = l = 4;\ U_4 = 4\mu_B B$. The level of lowest energy is for the smallest m_l, which is $m_l = -l = -4;\ U_{-4} = -4\mu_B B$. The separation between these two levels is $U_4 - U_{-4} = 8\mu_B B = 8(3.47\times10^{-5} \text{ eV}) = 2.78\times10^{-4} \text{ eV}.$

EVALUATE: The energy separations are proportional to the magnetic field. The energy of the $n = 5$ level in the absence of the external magnetic field is $(-13.6\text{ eV})/5^2 = -0.544\text{ eV},$ so the interaction energy with the magnetic field is much less than the binding energy of the state.

41.24. **IDENTIFY:** The effect of the magnetic field on the energy levels is described by Eq. (41.36). In a transition m_l must change by 0 or ± 1.

SET UP: For a 2*p* state, m_l can be $0, \pm 1$. For a 1*s* state, m_l must be zero.

EXECUTE: **(a)** There are three different transitions that are consistent with the selection rules. The initial m_l values are 0, ± 1; and the final m_l value is 0.

(b) The transition from $m_l = 0$ to $m_l = 0$ produces the same wavelength (122 nm) that was seen without the magnetic field.

(c) The larger wavelength (smaller energy) is produced from the $m_l = -1$ to $m_l = 0$ transition.

(d) The shorter wavelength (greater energy) is produced from the $m_l = +1$ to $m_l = 0$ transition.

EVALUATE: The magnetic field increases the energy of the $m_l = 1$ state, decreases the energy for $m_l = -1$ and leaves the $m_l = 0$ state unchanged.

41.25. **IDENTIFY** and **SET UP:** For a classical particle $L = I\omega$. For a uniform sphere with mass *m* and radius *R*, $I = \frac{2}{5}mR^2,$ so $L = \left(\frac{2}{5}mR^2\right)\omega.$ Solve for ω and then use $v = r\omega$ to solve for *v*.

EXECUTE: **(a)** $L = \sqrt{\frac{3}{4}}\hbar,$ so $\frac{2}{5}mR^2\omega = \sqrt{\frac{3}{4}}\hbar.$

$$\omega = \frac{5\sqrt{3/4}\hbar}{2mR^2} = \frac{5\sqrt{3/4}(1.055\times10^{-34}\text{ J}\cdot\text{s})}{2(9.109\times10^{-31}\text{ kg})(1.0\times10^{-17}\text{ m})^2} = 2.5\times10^{30}\text{ rad/s}.$$

(b) $v = r\omega = (1.0\times10^{-17}\text{ m})(2.5\times10^{30}\text{ rad/s}) = 2.5\times10^{13}\text{ m/s}.$

EVALUATE: This is much greater than the speed of light *c*, so the model cannot be valid.

41.26. **IDENTIFY:** The transition energy ΔE of the atom is related to the wavelength λ of the photon by $\Delta E = \frac{hc}{\lambda}.$ For an electron in a magnetic field the spin magnetic interaction energy is $\pm\mu_{\text{B}}B.$ Therefore the effective magnetic field is given by $\Delta E = 2\mu_{\text{B}}B$ when ΔE is produced by the hyperfine interaction.

SET UP: $\mu_{\text{B}} = 5.788\times10^{-5}\text{eV/T}.$

EXECUTE: **(a)** $\lambda = \frac{hc}{\Delta E} = \frac{(4.136\times10^{-15}\text{ eV}\cdot\text{s})(3.00\times10^8\text{ m/s})}{(5.9\times10^{-6}\text{ eV})} = 21\text{ cm},$

$f = \frac{c}{\lambda} = \frac{(3.00\times10^8\text{ m/s})}{0.21\text{ m}} = 1.4\times10^9\text{ Hz},$ a short radio wave.

(b) The effective field is $B \cong \Delta E/2\mu_{\text{B}} = 5.1\times10^{-2}\text{ T},$ far smaller than that found in Example 41.7 for spin-orbit coupling.

EVALUATE: The level splitting due to the hyperfine interaction is much smaller than the level splittings due to the spin-orbit interaction.

41.27. **IDENTIFY** and **SET UP:** The interaction energy is $U = -\vec{\boldsymbol{\mu}}\cdot\vec{\boldsymbol{B}},$ with μ_z given by $\mu_z = -(2.00232)\left(\frac{e}{2m}\right)S_z.$

EXECUTE: $U = -\vec{\boldsymbol{\mu}}\cdot\vec{\boldsymbol{B}} = +\mu_z B,$ since the magnetic field is in the negative *z*-direction.

$$\mu_z = -(2.00232)\left(\frac{e}{2m}\right)S_z,\text{ so } U = -(2.00232)\left(\frac{e}{2m}\right)S_z B.$$

$$S_z = m_s\hbar, \text{ so } U = -2.00232\left(\frac{e\hbar}{2m}\right)m_s B.$$

$$\frac{e\hbar}{2m} = \mu_B = 5.788\times10^{-5} \text{ eV/T}.$$

$$U = -2.00232\mu_B m_s B.$$

The $m_s = +\frac{1}{2}$ level has lower energy.

$$\Delta U = U(m_s = -\tfrac{1}{2}) - U(m_s = +\tfrac{1}{2}) = -2.00232\ \mu_B B(-\tfrac{1}{2} - (+\tfrac{1}{2})) = +2.00232\ \mu_B B.$$

$$\Delta U = +2.00232(5.788\times10^{-5} \text{ eV/T})(1.45 \text{ T}) = 1.68\times10^{-4} \text{ eV}.$$

EVALUATE: The interaction energy with the electron spin is the same order of magnitude as the interaction energy with the orbital angular momentum for states with $m_l \neq 0$. But a 1*s* state has $l = 0$ and $m_l = 0$, so there is no orbital magnetic interaction.

41.28. IDENTIFY: Apply the equation $\mu_z = -(2.00232)\dfrac{e}{2m}S_z$ with $S_z = -\dfrac{\hbar}{2}$.

SET UP: $\mu_B = \dfrac{e\hbar}{2m} = 5.788\times10^{-5}$ eV/T.

EXECUTE: **(a)** $U = +(2.00232)\left(\dfrac{e}{2m}\right)\left(\dfrac{-\hbar}{2}\right)B = -\dfrac{2.00232}{2}\mu_B B.$

$U = -\dfrac{2.00232}{2}(5.788\times10^{-5} \text{ eV/T})(1.60 \text{ T}) = -9.27\times10^{-5} \text{ eV}.$

(b) Since $n = 1$, $l = 0$, so there is no orbital magnetic dipole interaction. But if $n \neq 1$ there could be orbital magnetic dipole interaction, since $l < n$ would then allow for $l \neq 0$.

EVALUATE: The energy of the $m_s = -\frac{1}{2}$ state is lowered in the magnetic field. The energy of the $m_s = +\frac{1}{2}$ state is raised.

41.29. IDENTIFY: The ten lowest energy levels for electrons are in the $n = 1$ and $n = 2$ shells.

SET UP: $l = 0, 1, 2, \ldots, n-1.$ $m_l = 0, \pm1, \pm2, \ldots, \pm l.$ $m_s = \pm\frac{1}{2}.$

EXECUTE: $n = 1, l = 0, m_l = 0, m_s = \pm\frac{1}{2}$: 2 states. $n = 2, l = 0, m_l = 0, m_s = \pm\frac{1}{2}$: 2 states.

$n = 2, l = 1, m_l = 0, \pm1, m_s = \pm\frac{1}{2}$: 6 states.

EVALUATE: The ground state electron configuration for neon is $1s^2 2s^2 2p^6$. The electron configuration specifies the *n* and *l* quantum numbers for each electron.

41.30. IDENTIFY: Fill the subshells in the order of increasing energy. An *s* subshell holds 2 electrons, a *p* subshell holds 6, and a *d* subshell holds 10 electrons.

SET UP: Germanium has 32 electrons.

EXECUTE: The electron configuration is $1s^2 2s^2 2p^6 3s^2 3p^6 4s^2 3d^{10} 4p^2$.

EVALUATE: The electron configuration is that of zinc $(Z = 30)$ plus two electrons in the 4*p* subshell.

41.31. IDENTIFY: Write out the electron configuration for ground-state beryllium.

SET UP: Beryllium has 4 electrons.

EXECUTE: **(a)** $1s^2 2s^2$.

(b) $1s^2 2s^2 2p^6 3s^2$. $Z = 12$ and the element is magnesium.

(c) $1s^2 2s^2 2p^6 3s^2 3p^6 4s^2$. $Z = 20$ and the element is calcium.

EVALUATE: Beryllium, calcium, and magnesium are all in the same column of the periodic table.

41.32. IDENTIFY: Write out the electron configuration for ground-state carbon.
SET UP: Carbon has 6 electrons.
EXECUTE: (a) $1s^2 2s^2 2p^2$.
(b) The element of next larger Z with a similar electron configuration has configuration $1s^2 2s^2 2p^6 3s^2 3p^2$. $Z = 14$ and the element is silicon.
EVALUATE: Carbon and silicon are in the same column of the periodic table.

41.33. IDENTIFY and **SET UP:** The energy of an atomic level is given in terms of n and Z_{eff} by $E_n = -\left(\dfrac{Z_{\text{eff}}^2}{n^2}\right)(13.6 \text{ eV})$. The ionization energy for a level with energy $-E_n$ is $+E_n$.

EXECUTE: $n = 5$ and $\text{Z}_{\text{eff}} = 2.771$ gives $E_5 = -\dfrac{(2.771)^2}{5^2}(13.6 \text{ eV}) = -4.18 \text{ eV}$.

The ionization energy is 4.18 eV.
EVALUATE: The energy of an atomic state is proportional to Z_{eff}^2.

41.34. IDENTIFY and **SET UP:** Apply $E_n = -\left(\dfrac{Z_{\text{eff}}^2}{n^2}\right)(13.6 \text{ eV})$.

EXECUTE: For the $4s$ state, $E = -4.339$ eV and $Z_{\text{eff}} = 4\sqrt{(-4.339)/(-13.6)} = 2.26$. Similarly, $Z_{\text{eff}} = 1.79$ for the $4p$ state and 1.05 for the $4d$ state.
EVALUATE: The electrons in the states with higher l tend to be farther away from the filled subshells and the screening is more complete.

41.35. IDENTIFY and **SET UP:** Use the exclusion principle to determine the ground-state electron configuration, as in Table 41.3 in the textbook. Estimate the energy by estimating Z_{eff}, taking into account the electron screening of the nucleus.
EXECUTE: (a) $Z = 7$ for nitrogen so a nitrogen atom has 7 electrons. N^{2+} has 5 electrons: $1s^2 2s^2 2p$.
(b) $Z_{\text{eff}} = 7 - 4 = 3$ for the $2p$ level.

$$E_n = -\left(\frac{Z_{\text{eff}}^2}{n^2}\right)(13.6 \text{ eV}) = -\frac{3^2}{2^2}(13.6 \text{ eV}) = -30.6 \text{ eV}.$$

(c) $Z = 15$ for phosphorus so a phosphorus atom has 15 electrons.
P^{2+} has 13 electrons: $1s^2 2s^2 2p^6 3s^2 3p$.
(d) $Z_{\text{eff}} = 15 - 12 = 3$ for the $3p$ level.

$$E_n = -\left(\frac{Z_{\text{eff}}^2}{n^2}\right)(13.6 \text{ eV}) = -\frac{3^2}{3^2}(13.6 \text{ eV}) = -13.6 \text{ eV}.$$

EVALUATE: In these ions there is one electron outside filled subshells, so it is a reasonable approximation to assume full screening by these inner-subshell electrons.

41.36. IDENTIFY and **SET UP:** Apply Eq. (41.48) and solve for Z.

EXECUTE: $E_{K\alpha} \cong (Z-1)^2(10.2 \text{ eV})$. $Z \approx 1 + \sqrt{\dfrac{7.46\times10^3 \text{ eV}}{10.2 \text{ eV}}} = 28.0$, which corresponds to the element Nickel (Ni).
EVALUATE: We use $Z - 1$ rather than Z in the expression for the transition energy, in order to account for screening by the other K-shell electron.

41.37. **IDENTIFY** and **SET UP:** Apply $E_{K\alpha} \cong (Z-1)^2(10.2\text{ eV})$. $E = hf$ and $c = f\lambda$.

EXECUTE: **(a)** $Z = 20$: $f = (2.48\times10^{15}\text{ Hz})(20-1)^2 = 8.95\times10^{17}$ Hz.

$E = hf = (4.14\times10^{-15}\text{ eV}\cdot\text{s})(8.95\times10^{17}\text{ Hz}) = 3.71\text{ keV}$. $\lambda = \dfrac{c}{f} = \dfrac{3.00\times10^{8}\text{ m/s}}{8.95\times10^{17}\text{ Hz}} = 3.35\times10^{-10}$ m.

(b) $Z = 27$: $f = 1.68\times10^{18}$ Hz. $E = 6.96$ keV. $\lambda = 1.79\times10^{-10}$ m.

(c) $Z = 48$: $f = 5.48\times10^{18}$ Hz, $E = 22.7$ keV, $\lambda = 5.47\times10^{-11}$ m.

EVALUATE: f and E increase and λ decreases as Z increases.

41.38. **IDENTIFY:** The energies of the x rays will be equal to the energy differences between the shells. From its energy, we can calculate the wavelength of the x ray.

SET UP: $\Delta E = \dfrac{hc}{\lambda}$. A K_α x ray is produced in a $L \to K$ transition and a K_β x ray is produced in a $M \to K$ transition.

EXECUTE: K_α: $\Delta E = E_L - E_K = -12{,}000\text{ eV} - (-69{,}500\text{ eV}) = +57{,}500$ eV.

$$\lambda = \frac{hc}{\Delta E} = \frac{(4.136\times10^{-15}\text{ eV}\cdot\text{s})(3.00\times10^{8}\text{ m/s})}{57{,}500\text{ eV}} = 0.0216\text{ nm}.$$

K_β: $\Delta E = E_M - E_K = -2200\text{ eV} - (-69{,}500\text{ eV}) = +67{,}300$ eV.

$$\lambda = \frac{hc}{\Delta E} = \frac{(4.136\times10^{-15}\text{ eV}\cdot\text{s})(3.00\times10^{8}\text{ m/s})}{67{,}300\text{ eV}} = 0.0184\text{ nm}.$$

EVALUATE: These wavelengths are much shorter than the wavelengths in the visible spectrum of hydrogen.

41.39. **IDENTIFY:** The electrons cannot all be in the same state in a cubical box.

SET UP and **EXECUTE:** The ground state can hold 2 electrons, the first excited state can hold 6 electrons, and the second excited state can hold 6. Therefore, two electrons will be in the second excited state, which has energy $3E_{1,1,1}$.

EVALUATE: The second excited state is the third state, which has energy $3E_{1,1,1}$, as shown in Figure 41.4 in the textbook.

41.40. **IDENTIFY:** For a rectangular box having sides of lengths L_X, L_Y, and L_Z, the possible energy levels of an electron in the box are $E_{n_X,n_Y,n_Z} = \left(\dfrac{n_X^2}{L_X^2} + \dfrac{n_Y^2}{L_Y^2} + \dfrac{n_Z^2}{L_Z^2}\right)\dfrac{\pi^2\hbar^2}{2m}$, where n_X, n_Y, and n_Z = 1, 2, 3, …

SET UP: For this box, we know that $L_X = 0.600$ nm and $L_Y = L_Z = 2L_X = 1.20$ nm. Using $L_Y = L_Z = 2L_X$, the energy levels can be written as

$$E_{n_X,n_Y,n_Z} = \left(\frac{n_X^2}{L_X^2} + \frac{n_Y^2}{4L_Y^2} + \frac{n_Z^2}{4L_Z^2}\right)\frac{\pi^2\hbar^2}{2m} = (4n_X^2 + n_Y^2 + n_Z^2)\frac{\pi^2\hbar^2}{8mL_X^2} = (4n_X^2 + n_Y^2 + n_Z^2)E_0.$$

EXECUTE: First calculate E_0:

$$E_0 = \frac{\pi^2\hbar^2}{8mL_X^2} = \frac{\pi^2(1.055\times10^{-34}\text{ J}\cdot\text{s})^2}{8(9.109\times10^{-31}\text{ kg})(0.600\times10^{-9}\text{ m})^2} = 4.1846\times10^{-20}\text{ J} = 0.2612\text{ eV}.$$

First (lowest) state: $n_X = n_Y = n_Z = 1$, so the state is (1, 1, 1) and the energy is $E_{1,1,1}$. Using the information we have gives $E_{1,1,1} = [4(1^2) + 1^2 + 1^2]E_0 = 6E_0 = 6(0.2612\text{ eV}) = 1.57$ eV.
The degeneracy in just the quantum numbers is just 1 because there is only one set of quantum numbers that will give this energy. But the electron has 2 spin states, so the degeneracy is 2.
Second state: The quantum numbers are $n_X = 1$, $n_Y = 2$, $n_Z = 1$ and $n_X = 1$, $n_Y = 1$, $n_Z = 2$. Both sets give the same energy, so the degeneracy is 4 (including spin). The states are (1, 2, 1) and (1, 1, 2). The energy is $E_{1,2,1} = E_{1,1,2} = [4(1^2) + 1^2 + 2^2]E_0 = 9E_0 = 9(0.2612\text{ eV}) = 2.35$ eV.

Third state: The state is (1, 2, 2), and it has degeneracy 2 (including spin). The energy is $E_{1,2,2} = [4(1^2) + 2^2 + 2^2]E_0 = 12E_0 = 12(0.2612 \text{ eV}) = 3.13 \text{ eV}$.
Fourth state: The possibilities are (1, 3, 1) and (1, 1, 3), so the degeneracy is 4 (including spin). The energy is $E_{1,3,1} = E_{1,1,3} = [4(1^2) + 3^2 + 1^2]E_0 = 14E_0 = 14(0.2612 \text{ ev}) = 3.66 \text{ eV}$.
EVALUATE: These energy states are all higher than the $n = 3$ state of hydrogen, which is 1.51 eV.

41.41. **IDENTIFY:** Calculate the probability of finding a particle in a given region within a cubical box.
(a) SET UP and EXECUTE: The box has volume L^3. The specified cubical space has volume $(L/4)^3$. Its fraction of the total volume is $\dfrac{1}{64} = 0.0156$.

(b) SET UP and EXECUTE: $P = \left(\dfrac{2}{L}\right)^3 \left[\int_0^{L/4} \sin^2 \dfrac{\pi x}{L} dx\right]\left[\int_0^{L/4} \sin^2 \dfrac{\pi y}{L} dy\right]\left[\int_0^{L/4} \sin^2 \dfrac{\pi z}{L} dz\right]$.

From Example 41.1, each of the three integrals equals $\dfrac{L}{8} - \dfrac{L}{4\pi} = \dfrac{1}{2}\left(\dfrac{L}{2}\right)\left(\dfrac{1}{2} - \dfrac{1}{\pi}\right)$.

$$P = \left(\frac{2}{L}\right)^3 \left(\frac{L}{2}\right)^3 \left(\frac{1}{2}\right)^3 \left(\frac{1}{2} - \frac{1}{\pi}\right)^3 = 7.50 \times 10^{-4}.$$

EVALUATE: Note that this is the cube of the probability of finding the particle anywhere between $x = 0$ and $x = L/4$. This probability is much less that the fraction of the total volume that this space represents. In this quantum state the probability distribution function is much larger near the center of the box than near its walls.

(c) SET UP and EXECUTE: $|\psi_{2,1,1}|^2 = \left(\dfrac{L}{2}\right)^3 \left(\sin^2 \dfrac{2\pi x}{L}\right)\left(\sin^2 \dfrac{\pi y}{L}\right)\left(\sin^2 \dfrac{\pi z}{L}\right)$.

$$P = \left(\frac{2}{L}\right)^3 \left[\int_0^{L/4} \sin^2 \frac{2\pi x}{L} dx\right]\left[\int_0^{L/4} \sin^2 \frac{\pi y}{L} dy\right]\left[\int_0^{L/4} \sin^2 \frac{\pi z}{L} dz\right].$$

$$\left[\int_0^{L/4} \sin^2 \frac{\pi y}{L} dy\right] = \left[\int_0^{L/4} \sin^2 \frac{\pi z}{L} dz\right] = \frac{L}{2}\left(\frac{1}{2}\right)\left(\frac{1}{2} - \frac{1}{\pi}\right). \quad \int_0^{L/4} \sin^2 \frac{2\pi x}{L} dx = \frac{L}{8}.$$

$$P = \left(\frac{2}{L}\right)^3 \left(\frac{L}{2}\right)^2 \left(\frac{1}{2}\right)^2 \left(\frac{1}{2} - \frac{1}{\pi}\right)^2 \left(\frac{L}{8}\right) = 2.06 \times 10^{-3}.$$

EVALUATE: This is about a factor of three larger than the probability when the particle is in the ground state.

41.42. **IDENTIFY:** For a rectangular box having sides of lengths L_X, L_Y, and L_Z, the possible energy levels of an electron in the box are $E_{n_X,n_Y,n_Z} = \left(\dfrac{n_X^2}{L_X^2} + \dfrac{n_Y^2}{L_Y^2} + \dfrac{n_Z^2}{L_Z^2}\right)\dfrac{\pi^2\hbar^2}{2m}$, where n_X, n_Y, and $n_Z = 1, 2, 3, \ldots$

SET UP: For this box, we know that $L_X = L_Z$. We also know that the two lowest energy levels are 2.24 eV and 3.47 eV and both of these levels have degeneracy 2 including electron spin. Using $L_X = L_Z$, the energy levels can be written as $E_{n_X,n_Y,n_Z} = \left(\dfrac{n_X^2 + n_Z^2}{L_X^2} + \dfrac{n_Y^2}{L_Y^2}\right)\dfrac{\pi^2\hbar^2}{2m}$.

EXECUTE: **(a)** Looking at the possibilities for the quantum numbers, we see that the two lowest levels having degeneracy 2 are (1, 1, 1) and (1, 2, 1). Therefore $E_{1,1,1} = 2.24$ eV and $E_{1,2,1} = 3.47$ eV. (We cannot have $E_{1,1,2}$ because it is degenerate with $E_{2,1,1}$, so this state would have degeneracy 4 including spin.)
(b) Using the numbers we know gives $E_{1,1,1} = \left(\dfrac{1^2 + 1^2}{L_X^2} + \dfrac{1^2}{L_Y^2}\right)\dfrac{\pi^2\hbar^2}{2m}$ and $E_{1,2,1} = \left(\dfrac{1^2 + 1^2}{L_X^2} + \dfrac{2^2}{L_Y^2}\right)\dfrac{\pi^2\hbar^2}{2m}$.

Subtracting these two equations gives $\dfrac{3}{L_Y^2}\left(\dfrac{\pi^2\hbar^2}{2m}\right) = 3.47 \text{ eV} - 2.24 \text{ eV} = 1.23 \text{ eV}$.

Solving for L_Y gives $L_Y=\sqrt{\dfrac{3\pi^2\hbar^2}{2m(1.23\text{ eV})}}=9.58\times10^{-10}$ m = 0.958 nm. Now use this result to solve for L_X and L_Z. Using the $E_{1,1,1}$ equation gives $\dfrac{2}{L_X^2}=(2.24\text{ eV})\left(\dfrac{2\text{m}}{\pi^2\hbar^2}\right)-\dfrac{1}{L_Y^2}$. Using L_Y = 0.958 nm, gives $L_X=L_Z=0.641$ nm.

(c) The next higher energy state is (1, 1, 2) and (2, 1, 1), which has degeneracy 4 (including spin). The energy is $E_{1,1,2}=\left(\dfrac{1+2^2}{L_X^2}+\dfrac{1}{L_Y^2}\right)\left(\dfrac{\pi^2\hbar^2}{2m}\right)=\left[\dfrac{5}{(0.641\text{ nm})^2}+\dfrac{1}{(0.958\text{ nm})^2}\right]\left(\dfrac{\pi^2\hbar^2}{2m}\right)=5.00\text{ eV}=E_{2,1,1}.$

EVALUATE: The longest side of this box is about 9 times the diameter of the Bohr hydrogen atom, and the shorter sides are each about 6 times that diameter.

41.43. IDENTIFY: Calculate the probability of finding a particle in certain regions of a three-dimensional box.

SET UP: $\left|\psi_{1,1,1}\right|^2=\left(\dfrac{L}{2}\right)^3\left(\sin^2\dfrac{\pi x}{L}\right)\left(\sin^2\dfrac{\pi y}{L}\right)\left(\sin^2\dfrac{\pi z}{L}\right).$

EXECUTE: **(a)** $P=\left(\dfrac{2}{L}\right)^3\left[\int_0^{L/2}\sin^2\dfrac{\pi x}{L}dx\right]\left[\int_0^{L}\sin^2\dfrac{\pi y}{L}dy\right]\left[\int_0^{L}\sin^2\dfrac{\pi z}{L}dz\right].$

$\left[\int_0^{L}\sin^2\dfrac{\pi y}{L}dy\right]=\left[\int_0^{L}\sin^2\dfrac{\pi z}{L}dz\right]=\dfrac{L}{2}.\ \int_0^{L/2}\sin^2\dfrac{\pi x}{L}dx=\left[\dfrac{x}{2}-\dfrac{L}{4\pi}\sin\dfrac{2\pi x}{L}\right]_0^{L/2}=\left(\dfrac{L}{2}\right)\left(\dfrac{1}{2}\right).$

$$P=\left(\frac{2}{L}\right)^3\left(\frac{L}{2}\right)^3\left(\frac{1}{2}\right)=\frac{1}{2}=0.500.$$

(b) $P=\left(\dfrac{2}{L}\right)^3\left[\int_{L/4}^{L/2}\sin^2\dfrac{\pi x}{L}dx\right]\left[\int_0^{L}\sin^2\dfrac{\pi y}{L}dy\right]\left[\int_0^{L}\sin^2\dfrac{\pi z}{L}dz\right].$

$\left[\int_0^{L}\sin^2\dfrac{\pi y}{L}dy\right]=\left[\int_0^{L}\sin^2\dfrac{\pi z}{L}dz\right]=\dfrac{L}{2}.\ \int_{L/4}^{L/2}\sin^2\dfrac{\pi x}{L}dx=\left[\dfrac{x}{2}-\dfrac{L}{4\pi}\sin\dfrac{2\pi x}{L}\right]_{L/4}^{L/2}=\left(\dfrac{L}{2}\right)\left(\dfrac{1}{4}+\dfrac{1}{2\pi}\right).$

$$P=\left(\frac{2}{L}\right)^3\left(\frac{L}{2}\right)^3\left(\frac{1}{4}+\frac{1}{2\pi}\right)=\frac{1}{4}+\frac{1}{2\pi}=0.409.$$

EVALUATE: In Example 41.1 for this state the probability for finding the particle between $x=0$ and $x=L/4$ is 0.091. The sum of this result and our result in part (b) is $0.091+0.409=0.500$. This in turn equals the probability of finding the particle in half the box, as calculated in part (a).

41.44. IDENTIFY and SET UP: Evaluate $\partial^2\psi/\partial x^2$, $\partial^2\psi/\partial y^2$, and $\partial^2\psi/\partial z^2$ for the proposed ψ and put into Eq. (41.5). Use that ψ_{n_x}, ψ_{n_y}, and ψ_{n_z} are each solutions to Eq. (40.44).

EXECUTE: **(a)** $-\dfrac{\hbar^2}{2m}\left(\dfrac{\partial^2\psi}{\partial x^2}+\dfrac{\partial^2\psi}{\partial y^2}+\dfrac{\partial^2\psi}{\partial z^2}\right)+U\psi=E\psi.$

ψ_{n_x}, ψ_{n_y}, ψ_{n_z} are each solutions of Eq. (40.44), so $-\dfrac{\hbar^2}{2m}\dfrac{d^2\psi_{n_x}}{dx^2}+\dfrac{1}{2}k'x^2\psi_{n_x}=E_{n_x}\psi_{n_x}.$

$$-\frac{\hbar^2}{2m}\frac{d^2\psi_{n_y}}{dy^2}+\frac{1}{2}k'y^2\psi_{n_y}=E_{n_y}\psi_{n_y}.$$

$$-\frac{\hbar^2}{2m}\frac{d^2\psi_{n_z}}{dz^2}+\frac{1}{2}k'z^2\psi_{n_z}=E_{n_z}\psi_{n_z}.$$

$$\psi=\psi_{n_x}(x)\psi_{n_y}(y)\psi_{n_z}(z),\ U=\frac{1}{2}k'x^2+\frac{1}{2}k'y^2+\frac{1}{2}k'z^2.$$

$$\frac{\partial^2\psi}{\partial x^2}=\left(\frac{d^2\psi_{n_x}}{dx^2}\right)\psi_{n_y}\psi_{n_z},\ \frac{\partial^2\psi}{\partial y^2}=\left(\frac{d^2\psi_{n_y}}{dy^2}\right)\psi_{n_x}\psi_{n_z},\ \frac{\partial^2\psi}{\partial z^2}=\left(\frac{d^2\psi_{n_z}}{dz^2}\right)\psi_{n_x}\psi_{n_y}.$$

So, $$-\frac{\hbar^2}{2m}\left(\frac{\partial^2\psi}{\partial x^2}+\frac{\partial^2\psi}{\partial y^2}+\frac{\partial^2\psi}{\partial z^2}\right)+U\psi=\left(-\frac{\hbar^2}{2m}\frac{d^2\psi_{n_x}}{dx^2}+\frac{1}{2}k'x^2\psi_{n_x}\right)\psi_{n_y}\psi_{n_z}$$

$$+\left(-\frac{\hbar^2}{2m}\frac{d^2\psi_{n_y}}{dy^2}+\frac{1}{2}k'y^2\psi_{n_y}\right)\psi_{n_x}\psi_{n_z}+\left(-\frac{\hbar^2}{2m}\frac{d^2\psi_{n_z}}{dz^2}+\frac{1}{2}k'z^2\psi_{n_z}\right)\psi_{n_x}\psi_{n_y}$$

$$-\frac{\hbar^2}{2m}\left(\frac{\partial^2\psi}{\partial x^2}+\frac{\partial^2\psi}{\partial y^2}+\frac{\partial^2\psi}{\partial z^2}\right)+U\psi=(E_{n_x}+E_{n_y}+E_{n_z})\psi.$$

Therefore, we have shown that this ψ is a solution to Eq. (41.5), with energy

$$E_{n_xn_yn_z}=E_{n_x}+E_{n_y}+E_{n_z}=\left(n_x+n_y+n_z+\frac{3}{2}\right)\hbar\omega.$$

(b) and **(c)** The ground state has $n_x=n_y=n_z=0,$ so the energy is $E_{000}=\frac{3}{2}\hbar\omega.$ There is only one set of $n_x, n_y,$ and n_z that give this energy.

<u>First-excited state:</u> $n_x=1, n_y=n_z=0$ or $n_y=1, n_x=n_z=0$ or $n_z=1, n_x=n_y=0$ and

$$E_{100}=E_{010}=E_{001}=\tfrac{5}{2}\hbar\omega.$$

There are three different sets of $n_x,\ n_y,\ n_z$ quantum numbers that give this energy, so there are three different quantum states that have this same energy.

EVALUATE: For the three-dimensional isotropic harmonic oscillator, the wave function is a product of one-dimensional harmonic oscillator wavefunctions for each dimension. The energy is a sum of energies for three one-dimensional oscillators. All the excited states are degenerate, with more than one state having the same energy.

41.45. IDENTIFY: Find solutions to Eq. (41.5).

SET UP: $\omega_1=\sqrt{k_1'/m},\ \omega_2=\sqrt{k_2'/m}.$ Let $\psi_{n_x}(x)$ be a solution of Eq. (40.44) with $E_{n_x}=(n_x+\frac{1}{2})\,\hbar\omega_1, \psi_{n_y}(y)$ be a similar solution, and let $\psi_{n_z}(z)$ be a solution of Eq. (40.44) but with *z* as the independent variable instead of *x*, and energy $E_{n_z}=(n_z+\frac{1}{2})\hbar\omega_2.$

EXECUTE: **(a)** As in Problem 41.44, look for a solution of the form $\psi(x,y,z)=\psi_{n_x}(x)\psi_{n_y}(y)\psi_{n_z}(z).$

Then, $-\dfrac{\hbar^2}{2m}\dfrac{\partial^2\psi}{\partial x^2}=(E_{n_x}-\frac{1}{2}k_1'x^2)\psi$ with similar relations for $\dfrac{\partial^2\psi}{\partial y^2}$ and $\dfrac{\partial^2\psi}{\partial z^2}$. Adding,

$$-\frac{\hbar^2}{2m}\left(\frac{\partial^2\psi}{\partial x^2}+\frac{\partial^2\psi}{\partial y^2}+\frac{\partial^2\psi}{\partial z^2}\right)=(E_{n_x}+E_{n_y}+E_{n_z}-\tfrac{1}{2}k_1'x^2-\tfrac{1}{2}k_1'y^2-\tfrac{1}{2}k_2'z^2)\psi$$

$$=(E_{n_x}+E_{n_y}+E_{n_z}-U)\psi=(E-U)\psi$$

where the energy *E* is $E=E_{n_x}+E_{n_y}+E_{n_z}=\hbar\left[(n_x+n_y+1)\omega_1^2+(n_z+\frac{1}{2})\omega_2^2\right],$ with $n_x, n_y,$ and n_z all nonnegative integers.

(b) The ground level corresponds to $n_x=n_y=n_z=0,$ and $E=\hbar(\omega_1^2+\frac{1}{2}\omega_2^2).$ The first excited level corresponds to $n_x=n_y=0$ and $n_z=1,$ since $\omega_1^2>\omega_2^2,$ and $E=\hbar(\omega_1^2+\frac{3}{2}\omega_2^2).$

(c) There is only one set of quantum numbers for both the ground state and the first excited state.

EVALUATE: For the isotropic oscillator of Problem 41.44 there are three states for the first excited level but only one for the anisotropic oscillator.

41.46. **IDENTIFY:** This problem deals with a particle in a three-dimensional noncubical box.
SET UP: The energy levels are shown in Eq. (41.17) in textbook.
EXECUTE: **(a)** We want energy difference between the first excited energy level and the ground state. For this box, $L_Y = 2L_X$ and $L_Z = L_Y/3 = 2L_X/3$. In terms of L_X, the energies are

$$E_{n_X, n_Y, n_Z} = \left(\frac{n_X^2}{L_X^2} + \frac{n_Y^2}{4L_X^2} + \frac{9n_Z^2}{4L_X^2}\right)\frac{\pi^2\hbar^2}{2m}.$$

For the ground state, all the quantum numbers are equal to 1. For the first excited state, the smallest energy above the ground state is when $n_X = n_Z = 1$ and $n_Y = 2$. The energy difference between this state and ground is $\Delta E = E_{1,2,1} - E_{1,1,1}$. Using the above energy equation gives

$$\Delta E = \left[\left(\frac{1^2}{1} + \frac{2^2}{4} + \frac{9}{4}\right) - \left(\frac{1^2}{1} + \frac{1^2}{4} + \frac{9}{4}\right)\right]\frac{\pi^2\hbar^2}{2mL_X^2} = \frac{3\pi^2\hbar^2}{8mL_X^2}.$$

We could also express the result in terms of L_Y as $\Delta E = \dfrac{3\pi^2\hbar^2}{2mL_Y^2}$.

(b) This state is *not* degenerate because no other set of quantum numbers gives the same energy.
(c) We want to know where the probability distribution is greatest for the ground state.
Along the x-axis: $\sin \pi x/L_X$ is greatest when $\pi x/L_X = \pi/2$, which is when $x = L_X/2$.
Along the y-axis: $\sin \pi y/L_Y = \sin \pi y/2L_X$ is greatest when $\pi y/2L_X = \pi/2$, so $y = L_X$.
Along the z-axis: $\sin \pi z/L_Z = \sin \pi z/(2L_X/3)$ is greatest when $3\pi z/2L_X = \pi/2$, so $z = L_X/3$.
EVALUATE: The energy degeneracy is removed for a noncubical box because, due to the different dimensions, the quantum numbers all have different coefficients.

41.47. **IDENTIFY** and **SET UP:** To calculate the total number of states for the n^{th} principal quantum number shell we must add up all the possibilities. The spin states multiply everything by 2. The maximum l value is $(n-1)$, and each l value has $(2l+1)$ different m_l values.
EXECUTE: **(a)** The total number of states is

$$N = 2\sum_{l=0}^{n-1}(2l+1) = 2\sum_{l=0}^{n-1}1 + 4\sum_{l=0}^{n-1}l = 2n + \frac{4(n-1)(n)}{2} = 2n + 2n^2 - 2n = 2n^2.$$

(b) The $n = 5$ shell (O-shell) has 50 states.
EVALUATE: The $n = 1$ shell has 2 states, the $n = 2$ shell has 8 states, etc.

41.48. **IDENTIFY:** We are modeling nuclei in the sun as a particle in a three-dimensional cubical box.
SET UP and **EXECUTE:** **(a)** Assume the sun is all hydrogen with one electron each. The number N of electrons is $N = m_{\text{sun}}/m_{\text{proton}} = (2.0 \times 10^{30}\ \text{kg})/(1.7 \times 10^{-27}\ \text{kg}) = 1.2 \times 10^{57}$ electrons.
(b) The volume V each electron occupies is $V_{\text{sun}}/N = (4/3\ \pi R^3)/N = 4/3\ \pi(7000\ \text{km})^3/(1.2 \times 10^{57})$ $= 1.2 \times 10^{-36}\ \text{m}^3$.
(c) We want the volume per carbon atom. Each carbon atom has 6 electrons, so it occupies the space of 6 electrons. Hence its volume is $7.2 \times 10^{-36}\ \text{m}^3$.
(d) If the volume is a cube with side of length L, then $L^3 = 7.2 \times 10^{-36}\ \text{m}^3$, so $L = 1.9$ pm.
(e) n_X, n_Y, n_Z can be 1, 2, 3, ..., and $m_z = \pm\frac{1}{2}$. The possible states for 6 electrons are:
Lowest state: (1, 1, 1, ±½)
Possible higher states: (1, 1, 2, ±½), (1, 2, 1, ±½), (2, 1, 1, ±½).
(f) We want the highest energy. Use Eq. (41.16). These states are degenerate, so we only need to calculate one of them, and we use $L = 1.9$ pm.

$$E_{1,1,2} = \frac{\left(1^2 + 1^2 + 2^2\right)\pi^2\hbar^2}{2mL^2} = 1.0 \times 10^{-13}\ \text{J} = 630\ \text{keV}.$$

EVALUATE: Modeling such as this gives only very rough approximations, but it can give reasonable order-of-magnitude estimates.

41.49. **(a) IDENTIFY** and **SET UP:** The energy is given by $E_n = K_n + U_n = -\frac{1}{\epsilon_0^2}\frac{me^4}{8n^2h^2}$ from Chapter 39, which is identical to the Bohr energy levels for hydrogen from this chapter. The potential energy is given by $U(r) = \frac{1}{4\pi\epsilon_0}\frac{q_1 q_2}{r}$, with $q_1 = +Ze$ and $q_2 = -e$.

EXECUTE: $E_{1s} = -\frac{1}{(4\pi\epsilon_0)^2}\frac{me^4}{2\hbar^2}$; $U(r) = -\frac{1}{4\pi\epsilon_0}\frac{e^2}{r}$.

$$E_{1s} = U(r) \text{ gives } -\frac{1}{(4\pi\epsilon_0)^2}\frac{me^4}{2\hbar^2} = -\frac{1}{4\pi\epsilon_0}\frac{e^2}{r}.$$

$$r = \frac{(4\pi\epsilon_0)2\hbar^2}{me^2} = 2a.$$

EVALUATE: The turning point is twice the Bohr radius.

(b) IDENTIFY and **SET UP:** For the 1s state the probability that the electron is in the classically forbidden region is $P(r > 2a) = \int_{2a}^{\infty}|\psi_{1s}|^2 dV = 4\pi\int_{2a}^{\infty}|\psi_{1s}|^2 r^2 dr$. The normalized wave function of the 1s state of hydrogen is given in Example 41.4: $\psi_{1s}(r) = \frac{1}{\sqrt{\pi a^3}}e^{-r/a}$. Evaluate the integral; the integrand is the same as in Example 41.4.

EXECUTE: $P(r > 2a) = 4\pi\left(\frac{1}{\pi a^3}\right)\int_{2a}^{\infty} r^2 e^{-2r/a}dr$.

Use the integral formula $\int r^2 e^{-\alpha r}dr = -e^{-\alpha r}\left(\frac{r^2}{\alpha} + \frac{2r}{\alpha^2} + \frac{2}{\alpha^3}\right)$, with $\alpha = 2/a$.

$$P(r > 2a) = -\frac{4}{a^3}\left[e^{-2r/a}\left(\frac{ar^2}{2} + \frac{a^2 r}{2} + \frac{a^3}{4}\right)\right]_{2a}^{\infty} = +\frac{4}{a^3}e^{-4}(2a^3 + a^3 + a^3/4).$$

$$P(r > 2a) = 4e^{-4}(13/4) = 13e^{-4} = 0.238.$$

EVALUATE: These is a 23.8% probability of the electron being found in the classically forbidden region, where classically its kinetic energy would be negative.

41.50. **IDENTIFY:** At the r where $P(r)$ has its maximum value, $\frac{d(r^2|\psi|^2)}{dr} = 0$.

SET UP: From Example 41.4, $r^2|\psi|^2 = Cr^2 e^{-2r/a}$.

EXECUTE: $\frac{d(r^2|\psi|^2)}{dr} = Ce^{-2r/a}(2r - (2r^2/a))$. This is zero for $r = a$. Therefore, $P(r)$ has its maximum value at $r = a$, the distance of the electron from the nucleus in the Bohr model.

EVALUATE: Our result agrees with Figure 41.8 in the textbook.

41.51. **IDENTIFY:** At the value of r where $P(r)$ is a maximum, $\frac{dP}{dr} = 0$.

SET UP: $P(r) = \left(\frac{1}{24a^5}\right)r^4 e^{-r/a}$.

EXECUTE: $\frac{dP}{dr} = \left(\frac{1}{24a^5}\right)\left(4r^3 - \frac{r^4}{a}\right)e^{-r/a}$. $\frac{dP}{dr} = 0$ when $4r^3 - \frac{r^4}{a} = 0$; $r = 4a$. In the Bohr model, $r_n = n^2 a$ so $r_2 = 4a$, which agrees with the location of the maximum in $P(r)$.

EVALUATE: Our result agrees with Figure 41.8. The figure shows that $P(r)$ for the 2p state has a single maximum and no zeros except at $r = 0$ and $r \to \infty$.

41.52. **IDENTIFY:** This problem involves the Zeeman effect.
SET UP and **EXECUTE:** **(a)** We want the current. $\mu = IA = I\pi r^2$, so $I = \mu/\pi r^2$. Using μ from the problem gives

$$I = \frac{\frac{e}{2m_\mathrm{p}}S_z}{\pi r^2} = \frac{\left(\frac{e}{2m_\mathrm{p}}\right)\frac{\hbar}{2}}{\pi(0.85\ \mathrm{fm})^2} = 1100\ \mathrm{A}.$$

(b) We want the magnetic field at $x = 0.40a_0$ from the proton. Use Eq. (28.15) for a circular loop.

$$B_x = \frac{\mu_0 Ia^2}{2(x^2 + a^2)^{3/2}}.$$

In our case, a is the radius of the "loop" (which is the proton), so $a = R_\mathrm{p}$. $x = 0.40a_0 >> R_\mathrm{p}$. So

$$B_x = \frac{\mu_0 IR_\mathrm{p}^2}{2(0.40a_0)^3}.$$

Using $R_\mathrm{p} = 0.85$ fm, $I = 1100$ A, and $a_0 = 5.29 \times 10^{-11}$ m gives $B = 52$ mT.
(c) We want the potential energy due to the electron spin. Use Eq. (41.38) and $U = \pm\mu_z B$.

$$\mu_z = (2.00232)(e/2m)S_z \approx 2(e/2m)(\hbar/2) = \hbar e/2m = \mu_\mathrm{B}.$$

$$U = \mu_\mathrm{B}B = (5.788 \times 10^{-5}\ \mathrm{eV/T})(52\ \mathrm{mT}) = 3.0\ \mu\mathrm{eV}.$$

(d) We want the wavelength. $hc/\lambda = 2U$, so $\lambda = hc/2U = hc/[2(3.0\ \mu\mathrm{eV})] = 0.21\ \mathrm{m} = 21\ \mathrm{cm}$.
EVALUATE: **(e)** The observed radiation has a wavelength of precisely 21 cm, so it definitely could be from electron spin flip.

41.53. **IDENTIFY:** This problem is about the broadening of spectral lines in hydrogen due to spin-orbit coupling.
SET UP: The blue spectral line of wavelength 434 nm is due to a transition from the $n = 5$ to the $n = 2$ shell. Eq. (41.41) applies, with $l = 0, 1, 2, 3, 4$ and $j = |l \pm ½|$. In any transition $\Delta l = \pm 1$. Use Example 41.8 as a guide.
EXECUTE: **(a)** We want the number of states.
For the $n = 2$ level: $l = 0$ and 1. For $l = 0$, $j = |0 \pm ½| = ½$. For $l = 1$, $j = 1 \pm ½ = 1/2$ and 3/2. The possible states are (0, 1/2), (1, 1/2), and (1, 3/2), so there are 3 states.
For the $n = 5$ level: $l = 0, 1, 2, 3$, or 4. The possible values of j are
$l = 0$: $j = 1/2$
$l = 1$: $j = 1/2, 3/2$
$l = 2$: $j = 3/2, 5/2$
$l = 3$: $j = 5/2, 7/2$
$l = 4$: $j = 7/2, 9/2$
The possible states are (0, 1/2), (1, 1/2), (1, 3/2), (2, 3/2), (2, 5/2), (3, 5/2), (3, 7/2), (4, 7/2), (4, 9/2). There are a total of 9 states.
(b) We want the number of different energy levels for each value of n. From Eq. (41.41) we see that for a given n, the energy $E_{n,j}$ depends only on j. Therefore all states having the same n and j have the same energy.
$n = 2$ level: Since j has only 2 different possible values (1/2 and 3/2), there are only 2 different energy levels.
$n = 5$ level: Since j has 5 different values (1/2, 3/2, 5/2, 7/2, 9/2) there are 5 different energy levels.
For each energy level, we want its *difference* from $-(13.6\ \mathrm{eV})/n^2$. Call $E_n = -(13.6\ \mathrm{eV})/n^2$ and call the energy difference we want $\Delta E_{n,j} = E_{n,j} - E_n$, where $E_{n,j}$ is the energy of the (n, j) level as given in Eq. (41.41). For calculations use $\alpha^2 = 5.32514 \times 10^{-5}$. Using Eq. (41.41), we get

$$\Delta E_{n,j} = \frac{13.60\text{ eV}}{n^2}\left[1+\frac{\alpha^2}{n^2}\left(\frac{n}{j+1/2}-\frac{3}{4}\right)\right]-\left(\frac{13.60\text{ eV}}{n^2}\right) = -\frac{13.60\text{ eV}}{n^2}\frac{\alpha^2}{n^2}\left(\frac{n}{j+1/2}-\frac{3}{4}\right).$$

Simplifying to a working equation gives

$$\Delta E_{n,j} = -\frac{13.60\text{ eV}\alpha^2}{n^4}\left(\frac{n}{j+1/2}-\frac{3}{4}\right).$$

We now use this equation to calculate the energy *differences*. If $\Delta E_{n,j}$ is negative, the energy of the level is *less than* E_n.

<u>n = 2 level</u>: For $n = 2$ and $j = 1/2$, we have

$$\Delta E_{2,1/2} = -\frac{13.60\text{ eV}\alpha^2}{2^4}\left(\frac{2}{1/2+1/2}-\frac{3}{4}\right) = -5.658\times10^{-5}\text{ eV}.$$

For $n = 2$ and $j = 3/2$, we have

$$\Delta E_{2,3/2} = -\frac{13.60\text{ eV}\alpha^2}{2^4}\left(\frac{2}{3/2+1/2}-\frac{3}{4}\right) = -1.1316\times10^{-5}\text{ eV}.$$

<u>n = 5 level</u>: For $n = 5$ and $j = 1/2$, we have

$$\Delta E_{5,1/2} = -\frac{13.60\text{ eV}\alpha^2}{5^4}\left(\frac{5}{1/2+1/2}-\frac{3}{4}\right) = -4.11356\times10^{-5}\text{ eV}.$$

For $n = 5$ and $j = 3/2$, we have

$$\Delta E_{5,3/2} = -\frac{13.60\text{ eV}\alpha^2}{5^4}\left(\frac{5}{3/2+1/2}-\frac{3}{4}\right) = -1.69382\times10^{-5}\text{ eV}.$$

For $n = 5$ and $j = 5/2$, we have

$$\Delta E_{5,5/2} = -\frac{13.60\text{ eV}\alpha^2}{5^4}\left(\frac{5}{5/2+1/2}-\frac{3}{4}\right) = -8.87239\times10^{-6}\text{ eV}.$$

For $n = 5$, $j = 7/2$, we have

$$\Delta E_{5,7/2} = -\frac{13.60\text{ eV}\alpha^2}{5^4}\left(\frac{5}{7/2+1/2}-\frac{3}{4}\right) = -4.83949\times10^{-6}\text{ eV}.$$

For $n = 5$, $j = 9/2$, we have

$$\Delta E_{5,9/2} = -\frac{13.60\text{ eV}\alpha^2}{5^4}\left(\frac{5}{9/2+1/2}-\frac{3}{4}\right) = -2.41974\times10^{-6}\text{ eV}.$$

Notice that in every case, fine structure due to spin-orbit coupling makes the energy levels *more negative*, i.e. *lower*.

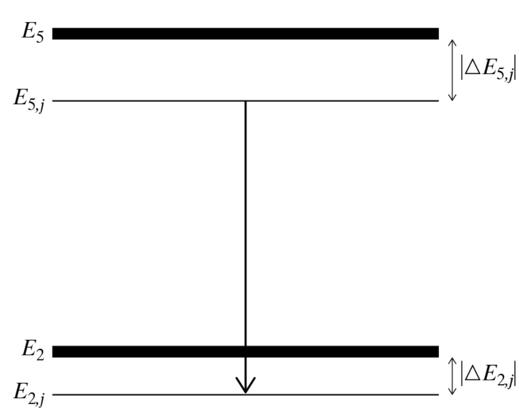

Figure 41.53

(c) We want the transition that emits the *shortest* wavelength of light. The shortest wavelength photon will have the highest energy, so it is between energy levels that have the *greatest* energy *difference* between them. Figure 41.53 illustrates a transition from a (5, j) level to a (2, j) level, where the two values of j are *not* the same. For the energy difference between these two levels to be as large as possible, $|\Delta E_{5,j}|$ should be the *smallest* it can be, and $|\Delta E_{2,j}|$ should be the *largest* it can be. But the transition must also obey $\Delta l = \pm 1$. For the $n = 2$ level, $l = 0$ or 1, which means that in the $n = 5$ level, $l =$ 0, 1, or 2. The energy levels, for a given n, depend only on j, so the j values for possible transitions that result in an energy difference and obey $\Delta l = \pm 1$ are

$$j = 1/2 \;\rightarrow\; j = 3/2 \quad (l = 0 \;\rightarrow\; l = 1)$$
$$j = 3/2 \;\rightarrow\; j = 1/2 \quad (l = 1 \;\rightarrow\; l = 0)$$
$$j = 5/2 \;\rightarrow\; j = 1/2 \quad (l = 2 \;\rightarrow\; l = 1)$$
$$j = 5/2 \;\rightarrow\; j = 3/2 \quad (l = 2 \;\rightarrow\; l = 1)$$

Using our results from part (b), we see that $|\Delta E_{2,j}|$ is greatest when $j = 1/2$ ($l = 1$), and $|\Delta E_{5,j}|$ is smallest when $j = 5/2$ ($l = 2$). Therefore the transition from the (5, 2, 5/2) level to the (2, 1, 1/2) level emits a photon of the greatest energy and therefore the shortest wavelength. The energy of this photon is $E_{\text{photon}} = E_5 + \Delta E_{5,5/2} - (E_2 + \Delta E_{2,1/2})$. Using this condition with $E_n = -(13.60\text{ eV})/n^2$ and our results from part (b), we have

$$E_{\text{photon}} = E_5 - E_2 + \Delta E_{5,5/2} - \Delta E_{2,1/2}$$

$$E_{\text{photon}} = -\frac{13.60\text{ eV}}{5^2} - \left(-\frac{13.60\text{ eV}}{2^2}\right) + (-8.87239\times10^{-5}\text{ eV}) - (-5.658\times10^{-5}\text{ eV}).$$

$$E_{\text{photon}} = \underbrace{2.856\text{ eV}}_{E_5\rightarrow E_2} + \underbrace{4.7708\times10^{-5}\text{ eV}}_{\Delta E_{5/2\rightarrow 1/2}}.$$

If there were no spin-orbit coupling, the wavelength of the photon would be 434 nm, as given in the problem. But, due to spin-orbit coupling, what appears as a single spectral line is made up of a number of lines, each of slightly different wavelength. To find the difference of the shortest-wavelength line from 434 nm, we use the approach in Example 41.8. The energy of the photon is $E = hc/\lambda$. As in the example, we can express this as

$$\Delta E = -\frac{hc}{\lambda^2}\Delta\lambda$$

$$\Delta\lambda = \frac{\lambda^2\Delta E}{hc} = -\frac{(434\text{ nm})^2(4.7708\times10^{-5}\text{ eV})}{(4.13567\times10^{-15}\text{ eV}\cdot\text{s})(2.998\times10^8\text{ m/s})} = -7.26\times10^{-12}\text{ m} = -7.26\times10^{-3}\text{ nm}.$$

(d) We want the longest wavelength photon. Refer to Figure 41.53. The longest wavelength is due to a transition between levels having the smallest energy difference between them. Using the allowed transitions from part (c), we see that the energy difference is *smallest* when $|\Delta E_{5,j}|$ is a *maximum* and $|E_{2,j}|$ is a *minimum*. For the allowed transitions, we see that $|E_{2,j}|$ is smallest when $j = 3/2$ ($l = 1$), and $|\Delta E_{5,j}|$ is largest when $j = 1/2$ ($l = 0$). So this transition is from the (5, 0, 1/2) level to the (2, 1, 3/2) level. Follow the same approach as for part (c), which gives

$$E_{\text{photon}} = E_5 - E_2 + \Delta E_{5,1/2} - \Delta E_{2,3/2}$$

$$E_{\text{photon}} = -\frac{13.60\text{ eV}}{5^2} - \left(-\frac{13.60\text{ eV}}{2^2}\right) + (-4.11356\times10^{-5}\text{ eV}) - (-1.1316\times10^{-5}\text{ eV}).$$

$$E_{\text{photon}} = \underbrace{2.856\text{ eV}}_{E_5\rightarrow E_2} - \underbrace{2.98196\times10^{-5}\text{ eV}}_{\Delta E_{1/2\rightarrow 3/2}}.$$

As before, we have

$$\Delta\lambda = -\frac{\lambda^2\Delta E}{hc} = -\frac{(434\text{ nm})^2(-2.98196\times10^{-5}\text{ eV})}{(4.13567\times10^{-15}\text{ eV.s})(2.998\times10^8\text{ m/s})} = +4.535\times10^{-12}\text{ m} = +4.54\times10^{-3}\text{ nm}.$$

(e) We want the total broadening of the spectral line. The width is the sum of the quantities we calculated in parts (c) and (d). The width is 7.26×10^{-3} nm + 4.54×10^{-3} nm = 1.18×10^{-2} nm.

EVALUATE: Notice that fine structure effects make vary small changes in the wavelength. That is why they are called *fine* structure.

41.54. **IDENTIFY:** The presence of an external magnetic field shifts the energy levels up or down, depending upon the value of m_l.

SET UP: The selection rules tell us that for allowed transitions, $\Delta l = 1$ and $\Delta m_l = 0$ or ± 1.

EXECUTE: **(a)** $E = hc/\lambda = (4.136\times10^{-15}\ \text{eV}\cdot\text{s})(3.00\times10^{8}\ \text{m/s})/(475.082\ \text{nm}) = 2.612\ \text{eV}$.

(b) For allowed transitions, $\Delta l = 1$ and $\Delta m_l = 0$ or ± 1. For the 3*d* state, $n = 3$, $l = 2$, and m_l can have the values $2, 1, 0, -1, -2$. In the 2*p* state, $n = 2$, $l = 1$, and m_l can be $1, 0, -1$. Therefore the 9 allowed transitions from the 3*d* state in the presence of a magnetic field are:

$$l = 2,\ m_l = 2 \to l = 1,\ m_l = 1$$
$$l = 2,\ m_l = 1 \to l = 1,\ m_l = 0$$
$$l = 2,\ m_l = 1 \to l = 1,\ m_l = 1$$
$$l = 2,\ m_l = 0 \to l = 1,\ m_l = 0$$
$$l = 2,\ m_l = 0 \to l = 1,\ m_l = 1$$
$$l = 2,\ m_l = 0 \to l = 1,\ m_l = -1$$
$$l = 2,\ m_l = -1 \to l = 1,\ m_l = 0$$
$$l = 2,\ m_l = -1 \to l = 1,\ m_l = -1$$
$$l = 2,\ m_l = -2 \to l = 1,\ m_l = -1$$

(c) $\Delta E = \mu_\text{B} B = (5.788\times10^{-5}\ \text{eV/T})(3.500\ \text{T}) = 0.000203\ \text{eV}$.

So the energies of the new states are $-8.50000\ \text{eV} + 0$ and $-8.50000\ \text{eV} \pm 0.000203\ \text{eV}$, giving energies of: -8.50020 eV, -8.50000 eV, and -8.49980 eV.

(d) The energy differences of the allowed transitions are equal to the energy differences if no magnetic field were present (2.61176 eV, from part (a)), and that value $\pm\Delta E$ (0.000203 eV, from part (c)). Therefore we get the following:

For $E = 2.61176\ \text{eV}$: $\lambda = 475.082\ \text{nm}$ (which was given).

For $E = 2.61176\ \text{eV} + 0.000203\ \text{eV} = 2.611963\ \text{eV}$:

$$\lambda = hc/E = (4.136\times10^{-15}\ \text{eV}\cdot\text{s})(3.00\times10^{8}\ \text{m/s})/(2.611963\ \text{eV}) = 475.045\ \text{nm}.$$

For $E = 2.61176\ \text{eV} - 0.000203\ \text{eV} = 2.61156\ \text{eV}$:

$$\lambda = hc/E = (4.136\times10^{-15}\ \text{eV}\cdot\text{s})(3.00\times10^{8}\ \text{m/s})/(2.61156\ \text{eV}) = 475.119\ \text{nm}.$$

EVALUATE: Even a strong magnetic field produces small changes in the energy levels, and hence in the wavelengths of the emitted light.

41.55. **IDENTIFY:** The presence of an external magnetic field shifts the energy levels up or down, depending upon the value of m_l.

SET UP: The energy difference due to the magnetic field is $\Delta E = \mu_\text{B} B$ and the energy of a photon is $E = hc/\lambda$.

EXECUTE: For the *p* state, $m_l = 0$ or ± 1, and for the *s* state $m_l = 0$. Between any two adjacent lines, $\Delta E = \mu_\text{B} B$. Since the change in the wavelength $(\Delta\lambda)$ is very small, the energy change (ΔE) is also very small, so we can use differentials. $E = hc/\lambda$. $|dE| = \dfrac{hc}{\lambda^2}d\lambda$ and $\Delta E = \dfrac{hc\Delta\lambda}{\lambda^2}$. Since $\Delta E = \mu_\text{B} B$, we get $\mu_B B = \dfrac{hc\Delta\lambda}{\lambda^2}$ and $B = \dfrac{hc\Delta\lambda}{\mu_B\lambda^2}$.

$$B = (4.136\times10^{-15}\ \text{eV}\cdot\text{s})(3.00\times10^{8}\ \text{m/s})(0.0462\ \text{nm})/(5.788\times10^{-5}\ \text{eV/T})(575.050\ \text{nm})^2 = 3.00\ \text{T}.$$

EVALUATE: Even a strong magnetic field produces small changes in the energy levels, and hence in the wavelengths of the emitted light.

41.56. IDENTIFY: Apply constant acceleration equations to relate F_z to the motion of an atom.

SET UP: According to the equation $\mu_z = -(2.00232)\left(\frac{e}{2m}\right)S_z$, the magnitude of μ_z is $|\mu_z| = 9.28\times10^{-24}\ \text{A}\cdot\text{m}^2$. The atomic mass of silver is 0.1079 kg/mol.

EXECUTE: The time required to transit the horizontal 50 cm region is $t = \frac{\Delta x}{v_x} = \frac{0.500\ \text{m}}{375\ \text{m/s}} = 1.333\ \text{ms}$.

The force required to deflect each spin component by 0.50 mm is

$F_z = ma_z = \pm m\frac{2\Delta z}{t^2} = \pm\left(\frac{0.1079\ \text{kg/mol}}{6.022\times10^{23}\ \text{atoms/mol}}\right)\frac{2(0.50\times10^{-3}\ \text{m})}{(1.333\times10^{-3}\ \text{s})^2} = \pm1.008\times10^{-22}\ \text{N}$. Thus, the required magnetic-field gradient is $\left|\frac{dB_z}{dz}\right| = \left|\frac{F_z}{\mu_z}\right| = \frac{1.008\times10^{-22}\ \text{N}}{9.28\times10^{-24}\ \text{J/T}} = 10.9\ \text{T/m}$, which rounds to 11 T/m.

EVALUATE: The two spin components are deflected in opposite directions.

41.57. IDENTIFY: We want to calculate the magnetic moment of a spinning sphere of charge.

SET UP: $\mu = g(Q/2M)L$. Follow the directions in each step of the problem.

EXECUTE: **(a)** $da = (Rd\theta)2\pi R\sin\theta d\theta = 2\pi R^2\sin\theta d\theta$.

(b) $dI = (\sigma dA)/T$ and $T = 2\pi/\omega$. Combining these relations with the result from part (a) gives

$$dI = \frac{\sigma 2\pi R^2 \sin\theta d\theta}{2\pi/\omega} = \sigma\omega R^2 \sin\theta d\theta.$$

(c) Using the results from parts (a) and (b) gives

$d\mu = AdI = \pi(R\sin\theta)^2\sigma\omega R^2\sin\theta d\theta = \pi\sigma\omega R^4\sin^3\theta d\theta$.

(d) Integrate to find the magnetic moment.

$$\mu = \int_0^\pi \pi\sigma\omega R^4\sin^3\theta\, d\theta = \pi\sigma\omega R^4\int_0^\pi \sin\theta(1-\cos^2\theta)d\theta = \frac{4\pi\sigma\omega R^4}{3}.$$

$$\sigma = Q/4\pi R^2 \text{ gives } \mu = \left(\frac{4\pi\omega R^4}{3}\right)\left(\frac{Q}{4\pi R^2}\right) = \frac{\omega R^2 Q}{3}.$$

(e) We now have a solid sphere. Consider the sphere to be a series of thin concentric shells each of thickness dr. Use the results of part (d) with $R \to r$ and $Q \to dq$ (the charge within the shell).

$$dq = \rho(r)dr = \rho(r)4\pi r^2 dr,\quad d\mu = \frac{\omega R^2 dq}{3} = \frac{\omega r^2}{3}\rho(r)4\pi r^2 dr,\quad \mu = \frac{4\pi\omega}{3}\int_0^R \rho(r)r^4\, dr.$$

(f) Wed want the g-factor. Use $L = I\omega$, $I = cMR^2$, and the results of part (e).

$$\mu = \frac{4\pi\omega}{3}\int_0^R \rho(r)r^4\, dr = g\frac{Q}{2M}L = g\frac{Q}{2M}I\omega = \frac{gQ}{2M}(cMR^2\omega).$$

$$g = \frac{8\pi}{3QcR^2}\int_0^R \rho(r)r^4\, dr.$$

(g) We want g if the solid sphere has uniform density. In this case the integral is

$$\int_0^R \rho(r)r^4\, dr = \frac{Q}{\frac{4}{3}\pi R^3}\frac{R^5}{5}.$$

Using $c = 2/5$ and solving the result in (f) for g gives $g = 1$.

EVALUATE: The result shows that for any spinning uniform solid sphere the g-factor is one.

41.58. **IDENTIFY:** The magnetic field at the center of a current loop of radius r is $B = \dfrac{\mu_0 I}{2r}$. $I = e\left(\dfrac{v}{2\pi r}\right)$.

SET UP: Use $L = mvr = \sqrt{l(l+1)}\hbar$. The Bohr radius is $n^2 a_0$.

EXECUTE: $v = \dfrac{\sqrt{l(l+1)}\hbar}{m(n^2 a_0)} = \dfrac{\sqrt{2}(6.63\times10^{-34}\ \text{J}\cdot\text{s})}{2\pi(9.11\times10^{-31}\ \text{kg})(4)(5.29\times10^{-11}\ \text{m})} = 7.74\times10^5\ \text{m/s}$. The magnetic field generated by the "moving" proton at the electron's position is

$$B = \frac{\mu_0 I}{2r} = \frac{\mu_0}{4\pi}\frac{ev}{r^2} = (10^{-7}\ \text{T}\cdot\text{m/A})\frac{(1.60\times10^{-19}\,\text{C})(7.74\times10^5\ \text{m/s})}{(4)^2(5.29\times10^{-11}\ \text{m})^2} = 0.277\ \text{T}.$$

EVALUATE: The effective magnetic field calculated in Example 41.7 for $3p$ electrons in sodium is much larger than the value we calculated for $2p$ electrons in hydrogen.

41.59. **IDENTIFY** and **SET UP:** m_s can take on four different values: $m_s = -\frac{3}{2},\ -\frac{1}{2},\ +\frac{1}{2}, +\frac{3}{2}$. Each nlm_l state can have four electrons, each with one of the four different m_s values. Apply the exclusion principle to determine the electron configurations.

EXECUTE: **(a)** For a filled $n=1$ shell, the electron configuration would be $1s^4$; four electrons and $Z=4$. For a filled $n=2$ shell, the electron configuration would be $1s^4 2s^4 2p^{12}$; twenty electrons and $Z=20$.

(b) Sodium has $Z=11$; eleven electrons. The ground-state electron configuration would be $1s^4 2s^4 2p^3$.

EVALUATE: The chemical properties of each element would be very different.

41.60. **IDENTIFY:** Apply $U = -\mu_z B$, where B is the effective magnetic field. $\Delta E = \dfrac{hc}{\lambda}$.

SET UP: $\mu_\text{B} = \dfrac{e\hbar}{2m} = \dfrac{eh}{4\pi m}$.

EXECUTE: The effective field is that which gives rise to the observed difference in the energy level transition, $B = \dfrac{\Delta E}{\mu_\text{B}} = \dfrac{hc}{\mu_\text{B}}\left(\dfrac{\lambda_1 - \lambda_2}{\lambda_1\lambda_2}\right) = \dfrac{4\pi mc}{e}\left(\dfrac{\lambda_1 - \lambda_2}{\lambda_1\lambda_2}\right)$. Substitution of numerical values gives $B = 7.28\times10^{-3}\ \text{T}$.

EVALUATE: The effective magnetic field we have calculated is much smaller than that calculated for sodium in Example 41.7.

41.61. **(a) IDENTIFY** and **SET UP:** The energy of the photon equals the transition energy of the atom: $\Delta E = hc/\lambda$. The energies of the states are given by $E_n = -\dfrac{13.60\ \text{eV}}{n^2}$.

EXECUTE: $E_n = -\dfrac{13.60\ \text{eV}}{n^2}$, so $E_2 = -\dfrac{13.60\ e\text{V}}{4}$ and $E_1 = -\dfrac{13.60\ \text{eV}}{1}$. Thus $\Delta E = E_2 - E_1$ gives

$$\Delta E = 13.60\ \text{eV}(-\tfrac{1}{4}+1) = \tfrac{3}{4}(13.60\ \text{eV}) = 10.20\ \text{eV} = (10.20\ \text{eV})(1.602\times10^{-19}\,\text{J/eV}) = 1.634\times10^{-18}\,\text{J}.$$

$$\lambda = \frac{hc}{\Delta E} = \frac{(6.626\times10^{-34}\ \text{J}\cdot\text{s})(2.998\times10^8\ \text{m/s})}{1.634\times10^{-18}\ \text{J}} = 1.22\times10^{-7}\ \text{m} = 122\ \text{nm}.$$

(b) IDENTIFY and **SET UP:** Calculate the change in ΔE due to the orbital magnetic interaction energy, $U = m_l\mu_\text{B}B$, and relate this to the shift $\Delta\lambda$ in the photon wavelength.

EXECUTE: The shift of a level due to the energy of interaction with the magnetic field in the z-direction is $U = m_l\mu_\text{B}B$. The ground state has $m_l = 0$, so is unaffected by the magnetic field. The $n=2$ initial state has $m_l = -1$, so its energy is shifted downward an amount

$$U = m_l \mu_B B = (-1)(9.274\times10^{-24}\ \text{A/m}^2)(2.20\ \text{T}) = (-2.040\times10^{-23}\ \text{J})(1\ \text{eV}/1.602\times10^{-19}\ \text{J})$$
$$= 1.273\times10^{-4}\ \text{eV}.$$

Note that the shift in energy due to the magnetic field is a very small fraction of the 10.2 eV transition energy. Problem 39.74c shows that in this situation $|\Delta\lambda/\lambda| = |\Delta E/E|$. This gives

$$|\Delta\lambda| = \lambda|\Delta E/E| = 122\ \text{nm}\left(\frac{1.273\times10^{-4}\ \text{eV}}{10.2\ \text{eV}}\right) = 1.52\times10^{-3}\ \text{nm} = 1.52\ \text{pm}.$$

EVALUATE: The upper level in the transition is lowered in energy so the transition energy is decreased. A smaller ΔE means a larger λ; the magnetic field increases the wavelength. The fractional shift in wavelength, $\Delta\lambda/\lambda$ is small, only 1.2×10^{-5}.

41.62. **IDENTIFY:** The interaction energy for an electron in a magnetic field is $U = -\mu_z B$, where μ_z is given by $\mu_z = -(2.00232)\left(\frac{e}{2m}\right)S_z$.

SET UP: $\Delta S_z = \hbar$.

EXECUTE: **(a)** $\Delta E = (2.00232)\frac{e}{2m}B\Delta S_z \approx \frac{e\hbar}{m}B = \frac{hc}{\lambda} \Rightarrow B = \frac{2\pi mc}{\lambda e}$.

(b) $B = \frac{2\pi(9.11\times10^{-31}\ \text{kg})(3.00\times10^8\ \text{m/s})}{(0.0420\ \text{m})(1.60\times10^{-19}\ \text{C})} = 0.255\ \text{T}.$

EVALUATE: As shown in Figure 41.18 in the textbook, the lower state in the transition has $m_s = -\frac{1}{2}$ and the upper state has $m_s = +\frac{1}{2}$.

41.63. **IDENTIFY** and **SET UP:** The energy due to the interaction of the electron with the magnetic field is $U = -\mu_z B$. In a transition from the $m_s = -\frac{1}{2}$ state to the $m_s = \frac{1}{2}$ state, $\Delta U = 2\mu_z B$. This energy difference is the energy of the absorbed photon. The energy of the photon is $E = hf$, and $f\lambda = c$. For an electron, $S_z = \hbar/2$.

EXECUTE: **(a)** First find the frequency for each wavelength in the table with the problem. For example for the first column, $f = c/\lambda = (2.998\times10^8\ \text{m/s})/(0.0214\ \text{m}) = 1.40\times10^{10}$ Hz. Doing this for all the wavelengths gives the values in the following table. Figure 41.63 shows the graph of f versus B for this data. The slope of the best-fit straight line is 2.84×10^{10} Hz/T.

B (T)	0.51	0.74	1.03	1.52	2.02	2.48	2.97
f (10^{10} Hz)	1.401	2.097	2.802	4.199	5.604	7.005	8.398

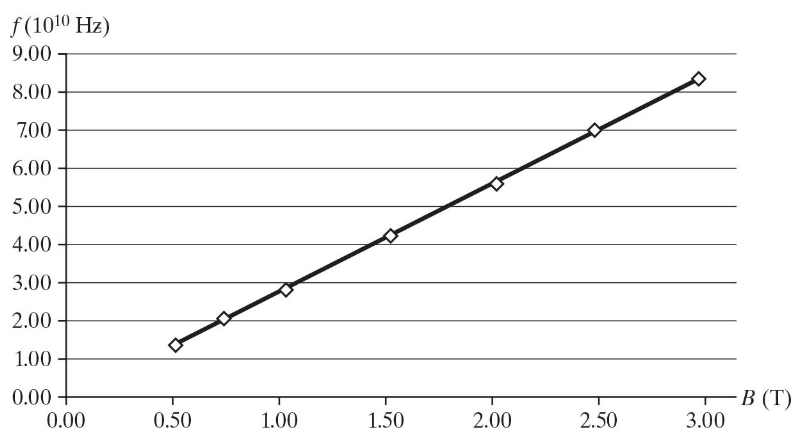

Figure 41.63

(b) The photon energy is $E = hf$, and that is the energy difference between the two levels. So $E = \Delta U = 2\mu_z B = hf$, which gives $f = \left(\dfrac{2\mu_z}{h}\right)B$. The graph of f versus B should be a straight line having slope equal to $2\mu_z/h$. Therefore the magnitude of the spin magnetic moment is $\mu_z = \frac{1}{2}h(\text{slope}) = \frac{1}{2}(6.626\times10^{-34}\ \text{J}\cdot\text{s})(2.84\times10^{10}\ \text{Hz/T}) = 9.41\times10^{-24}$ J/T.

(c) Using $\gamma = \dfrac{|\mu_z|}{|S_z|} = \dfrac{|\mu_z|}{\hbar/2}$ gives $\gamma = \dfrac{2(9.41\times10^{-24}\ \text{J/T})}{1.055\times10^{-34}\ \text{J}\cdot\text{s}} = 1.784\times10^{11}\ \text{Hz/T}$, which rounds to 1.78×10^{11} Hz/T. This gives $\dfrac{\gamma}{e/2m} = \dfrac{2\gamma m}{e} = \dfrac{2(1.784\times10^{11}\ \text{Hz/T})(9.11\times10^{-31}\ \text{kg})}{1.602\times10^{-19}\ \text{C}} = 2.03.$

EVALUATE: Our result of 2.03 for the gyromagnetic ratio for electron spin is in good agreement with the currently accepted value of 2.00232.

41.64. IDENTIFY: The photons have different energy due to spin-orbit coupling, which sifts the energy levels very slightly.

SET UP: Without spin-orbit coupling, the energy levels are given by $E_n = -\dfrac{13.60\ \text{eV}}{n^2}$. If we include this coupling, they are $E_{n,j} = -\dfrac{13.60\ \text{eV}}{n^2}\left[1+\dfrac{\alpha^2}{n^2}\left(\dfrac{n}{j+\frac{1}{2}}-\dfrac{3}{4}\right)\right]$. The energy of a photon due a transition involving energy change ΔE is $\Delta E = \dfrac{hc}{\lambda}$. Follow the ideas presented in Example 41.8, in which it was shown that $\Delta\lambda = -\dfrac{\lambda}{E_{\text{photon}}}\Delta E_{\text{photon}}$ since the energy shifts due to spin-orbit coupling are extremely small.

EXECUTE: For a transition from $n = 3$ to $n = 2$, without including fine structure, we use $E_n = -\dfrac{13.60\ \text{eV}}{n^2}$ to find the energy difference ΔE, whis is equal to the energy of the photon. This gives $E_{\text{photon}} = \Delta E = (-13.6\ \text{eV})(1/3^2 - 1/2^2) = 1.889$ eV.

The wavelength of this photon is

$\lambda = hc/E_{\text{photon}} = (4.136\times10^{-15}\ \text{eV}\cdot\text{s})(2.998\times10^8\ \text{m/s})/(1.889\ \text{eV}) = 6.56\times10^{-7}\ \text{m} = 656$ nm.

ΔE_{photon} is the energy difference between thre $E_{3,3/2}$ and the $E_{3,1/2}$ states. We calculate the energies of these states using $E_{n,j} = -\dfrac{13.60\ \text{eV}}{n^2}\left[1+\dfrac{\alpha^2}{n^2}\left(\dfrac{n}{j+\frac{1}{2}}-\dfrac{3}{4}\right)\right]$.

$$E_{3,3/2} = -\frac{13.60\ \text{eV}}{3^2}\left[1+\frac{(0.007297)^2}{3^2}\left(\frac{3}{\frac{3}{2}+\frac{1}{2}}-\frac{3}{4}\right)\right] = -\frac{13.60\ \text{eV}}{9}(1+4.437\times10^{-6}).$$

$$E_{3,1/2} = -\frac{13.60\ \text{eV}}{3^2}\left[1+\frac{(0.007297)^2}{3^2}\left(\frac{3}{\frac{1}{2}+\frac{1}{2}}-\frac{3}{4}\right)\right] = -\frac{13.60\ \text{eV}}{9}(1+13.312\times10^{-6}).$$

$\Delta E_{\text{photon}} = E_{3,3/2} - E_{3,1/2} = [(13.60\ \text{eV})/9](13.312\times10^{-6} - 4.437\times10^{-6}) = 1.341\times10^{-5}$ eV.

We now use $\Delta\lambda = -\dfrac{\lambda}{E_{\text{photon}}}\Delta E_{\text{photon}}$ to find the difference in the wavelengths.

$$\Delta\lambda = -\frac{656\ \text{nm}}{1.889\ \text{eV}}(1.341\times10^{-5}\ \text{eV}) = -4.66\times10^{-3}\ \text{nm} = -0.00466\ \text{nm}.$$

The photon for the transition from the $j = \frac{1}{2}$ state has the longer wavelength because the transition energy is smaller.

EVALUATE: The wavelength difference is only 0.00466 nm compared to a wavelength of 656 nm without spin-orbit coupling, so this is a very small effect.

41.65. IDENTIFY: The inner electrons shield much of the nuclear charge from the outer electrons, and this shielding affects the energy levels compared to the hydrogen levels. The atom behaves like hydrogen with an effective charge in the nucleus.

SET UP: The ionization energies are $E_n = \dfrac{Z_{\text{eff}}^2}{n^2}(13.6\text{ eV})$.

EXECUTE: **(a)** Make the conversions requested using the following conversion factor.

$$E(\text{eV/atom}) = E(\text{kJ/mol})\left(\frac{1\text{ mol}}{6.02214\times10^{23}\text{ atoms}}\right)\left(\frac{1000\text{ J}}{1\text{ kJ}}\right)\left(\frac{1\text{ eV}}{1.602\times10^{-19}\text{ J}}\right) = 0.010364E(\text{kJ/mol}).$$

Li: E = (0.010364)(520.2 kJ/mol) = 5.391 eV
Na: E = (0.010364)(495.8 kJ/mol) = 5.139 eV
K: E = (0.010364)(418.8 kJ/mol) = 4.341 eV
Rb: E = (0.010364)(403.0 kJ/mol) = 4.177 eV
Cs: E = (0.010364)(375.7 kJ/mol) = 3.894 eV
Fr: E = (0.010364)(380 kJ/mol) = 3.9 eV.

(b) From the periodic chart in the Appendix, we get the following information.

Li: $Z = 3$, $n = 2$
Na: $Z = 11$, $n = 3$
K: $Z = 19$, $n = 4$
Rb: $Z = 37$, $n = 5$
Cs: $Z = 55$, $n = 6$
Fr: $Z = 87$, $n = 7$.

(c) Use $E_n = \dfrac{Z_{\text{eff}}^2}{n^2}(13.6\text{ eV})$ and the values of n in part (b) to calculate Z_{eff}. For example, for Li we have

$5.391\text{ eV} = \dfrac{Z_{\text{eff}}^2}{2^2}(13.6\text{ eV}) \rightarrow Z_{\text{eff}} = 1.26$, and for Na we have

$5.139\text{ eV} = \dfrac{Z_{\text{eff}}^2}{3^2}(13.6\text{ eV}) \rightarrow Z_{\text{eff}} = 1.84$. Doing this for the other atoms gives

Li: $Z_{\text{eff}} = 1.26$
Na: $Z_{\text{eff}} = 1.84$
K: $Z_{\text{eff}} = 2.26$
Rb: $Z_{\text{eff}} = 2.77$
Cs: $Z_{\text{eff}} = 3.21$
Fr: $Z_{\text{eff}} = 3.8$.

EVALUATE: **(d)** We can see that Z_{eff} increases as Z increases. The outer (valence) electron has increasing probability density within the inner shells as Z increases, and therefore it "sees" more of the nuclear charge.

41.66. IDENTIFY and SET UP: The energy levels of a particle in a cubical box of length L are $E_{n_X,n_Y,n_Z} = \dfrac{(n_X^2+n_Y^2+n_Z^2)\pi^2\hbar^2}{2mL^2}$. The longest wavelength absorbed is for the smallest energy transition, which is between the ground state (1, 1, 1) and the next higher state (2, 1, 1). The energy absorbed by the photon is $\Delta E = \dfrac{hc}{\lambda}$.

EXECUTE: **(a)** The lowest energy transition is $\Delta E = \left[(2^2+1^2+1^2)-(1^2+1^2+1^2)\right]\dfrac{\pi^2\hbar^2}{2mL^2}$, and this is equal to the energy of the photon $\Delta E = \dfrac{hc}{\lambda}$. So, $\dfrac{hc}{624\text{ nm}} = \dfrac{3\pi^2\hbar^2}{2mL^2} = \dfrac{3h^2}{8mL^2}$, which gives

$L = \sqrt{\dfrac{3h(624\text{ nm})}{8mc}}$.

$$L = \sqrt{\frac{3(6.626\times10^{-34}\text{ J}\cdot\text{s})(624\text{ nm})}{8(9.11\times10^{-31}\text{ kg})(3.00\times10^8\text{ m/s})}} = 7.53\times10^{-10}\text{ m} = 0.753\text{ nm}.$$

(b) The final state is now *n*. Call the wavelength in part (a) λ_1 and the one in part (b) λ_2. From part (a) we have $\dfrac{hc}{\lambda_1} = \dfrac{3\pi^2\hbar^2}{2mL^2}$ and for part (b) we have $\dfrac{hc}{\lambda_2} = (n^2-3)\dfrac{\pi^2\hbar^2}{2mL^2}$. Diving these two equations gives

$\dfrac{hc/\lambda_2}{hc/\lambda_1} = \dfrac{\lambda_1}{\lambda_2} = \dfrac{624}{234} = \dfrac{n^2-3}{3}$. Solving for *n* gives $n^2 = 3 + 3(624/234) = 3 + 8 = 11$.

There are 3 possibilities: (1, 1, 3), (1, 3, 1), and (3, 1, 1), so the degeneracy is 6 including spin.
EVALUATE: The dimensions of this box are around 7 times the diameter of the Bohr hydrogen atom, which is reasonable.

41.67. **IDENTIFY:** This problem deals with the entanglement of three spin-3/2 particles.
SET UP: $s_z = m_z\hbar$, $m_z = \pm1/2, \pm3/2$.

EXECUTE: **(a)** These particles have spin 3/2, so their spin magnitude *S* is

$S = \sqrt{\dfrac{3}{2}\left(\dfrac{3}{2}+1\right)}\,\hbar = \sqrt{15/4}\,\hbar$.

(b) No particles can have identical states. We follow the reasoning of Section 41.8 in the textbook. For simplicity call the states $A = 1/2$, $B = -1/2$, $C = -3/2$. The possible combinations of *ABC* are *ABC*, *ACB*, *BAC*, *BCA*, *CAB*, and *CBA*. In terms of the wave functions, the normalized wave functions are

$$\psi = \frac{1}{\sqrt{6}}\big(\psi_{+1/2}\psi_{-1/2}\psi_{-3/2} - \psi_{+1/2}\psi_{-3/2}\psi_{-1/2} + \psi_{-1/2}\psi_{+1/2}\psi_{-3/2} - \psi_{+1/2}\psi_{-3/2}\psi_{+1/2} + \psi_{-3/2}\psi_{+1/2}\psi_{-1/2}$$
$$-\psi_{-3/2}\psi_{-1/2}\psi_{+1/2}\big).$$

The factor of $1/\sqrt{6}$ is present for normalization because the probability is proportional to the square of the wave function.
(c) Particle *A* has $m_z = +1/2$, but the other two could have $m_z = -3/2$ or $-1/2$. So the wave function is now $\psi = \dfrac{1}{\sqrt{2}}\big(\psi_{+1/2}\psi_{-3/2}\psi_{-1/2} - \psi_{+1/2}\psi_{+1/2} + \psi_{-3/2}\big)$.
(d) Particle *A* has $m_z = +1/2$, so particle *B* cannot have $m_z = +1/2$. But it could have $m_z = -1/2$ or $-3/2$. None of them can have $m_z = +3/2$. So the probabilities are 1/2, 0, 1/2, 0.
(e) Now we know that particle *C* has $m_z = -3/2$, so the wave functions are $\psi = \psi_{+1/2}\,\psi_{-1/2}\psi_{-3/2}$.
(f) We know that $m_z = -1/2$ for particle *B*, so the probabilities are 0, 1, 0, 0.
EVALUATE: We could not draw all these conclusions if the particles were not entangled.

41.68. **IDENTIFY** and **SET UP:** The potential $U(x) = \frac{1}{2}k'x^2$ is that of a simple harmonic oscillator. Treated quantum mechanically (see Section 40.5) each *energy* state has energy $E_n = \hbar\omega(n+\frac{1}{2})$. Since electrons obey the exclusion principle, this allows us to put *two* electrons (one for each $m_s = \pm\frac{1}{2}$) for every value of *n*—each quantum state is then defined by the ordered pair of quantum numbers (n, m_s).

EXECUTE: By placing two electrons in each energy level the lowest energy is

$$2\left(\sum_{n=0}^{N-1} E_n\right) = 2\left(\sum_{n=0}^{N-1} \hbar\omega(n+\tfrac{1}{2})\right) = 2\hbar\omega\left[\sum_{n=0}^{N-1} n + \sum_{n=0}^{N-1} \tfrac{1}{2}\right] = 2\hbar\omega\left[\frac{(N-1)(N)}{2} + \frac{N}{2}\right] =$$

$\hbar\omega[N^2 - N + N] = \hbar\omega N^2 = \hbar N^2\sqrt{\dfrac{k'}{m}}$. Here we realize that the first value of n is zero and the last value of n is $N-1$, giving us a total of N energy levels filled.

EVALUATE: The minimum energy for one electron moving in this potential is $\frac{1}{2}\hbar\omega$, with $\omega = \sqrt{\dfrac{k'}{m}}$. For $2N$ electrons the minimum energy is larger than $(2N)(\frac{1}{2}\hbar\omega)$, because only two electrons can be put into each energy state. For example, for $N = 2$ (4 electrons), there are two electrons in the $E = \frac{1}{2}\hbar\omega$ energy state and two in the $\frac{3}{2}\hbar\omega$ state, for a total energy of $2(\frac{1}{2}\hbar\omega) + 2(\frac{3}{2}\hbar\omega) = 4\hbar\omega$, which is in agreement with our general result.

41.69. IDENTIFY and **SET UP:** Apply Newton's second law and Bohr's quantization to one of the electrons.

EXECUTE: **(a)** Apply Coulomb's law to the orbiting electron and set it equal to the centripetal force. There is an attractive force with charge $+2e$ a distance r away and a repulsive force a distance $2r$ away. So, $\dfrac{(+2e)(-e)}{4\pi\epsilon_0 r^2} + \dfrac{(-e)(-e)}{4\pi\epsilon_0 (2r)^2} = \dfrac{-mv^2}{r}$. But, from the quantization of angular momentum in the first Bohr orbit, $L = mvr = \hbar \Rightarrow v = \dfrac{\hbar}{mr}$. So, $\dfrac{-2e^2}{4\pi\epsilon_0 r^2} + \dfrac{e^2}{4\pi\epsilon_0 (2r)^2} = \dfrac{-mv^2}{r} = \dfrac{-m\left(\dfrac{\hbar}{mr}\right)^2}{r} = -\dfrac{\hbar^2}{mr^3}$

$\Rightarrow \dfrac{-7}{4}\dfrac{e^2}{r^2} = -\dfrac{4\pi\epsilon_0 \hbar^2}{mr^3}$. $r = \dfrac{4}{7}\left(\dfrac{4\pi\epsilon_0 \hbar^2}{me^2}\right) = \dfrac{4}{7}a_0 = \dfrac{4}{7}(0.529\times10^{-10}\text{ m}) = 3.02\times10^{-11}$ m. And

$$v = \frac{\hbar}{mr} = \frac{7}{4}\frac{\hbar}{ma_0} = \frac{7}{4}\frac{(1.054\times10^{-34}\text{ J}\cdot\text{s})}{(9.11\times10^{-31}\text{ kg})(0.529\times10^{-10}\text{ m})} = 3.83\times10^6\text{ m/s}.$$

(b) $K = 2(\frac{1}{2}mv^2) = 9.11\times10^{-31}\text{ kg }(3.83\times10^6\text{ m/s})^2 = 1.34\times10^{-17}\text{ J} = 83.5\text{ eV}$.

(c) $U = 2\left(\dfrac{-2e^2}{4\pi\epsilon_0 r}\right) + \dfrac{e^2}{4\pi\epsilon_0 (2r)} = \dfrac{-4e^2}{4\pi\epsilon_0 r} + \dfrac{e^2}{4\pi\epsilon_0 (2r)} = \dfrac{-7}{2}\left(\dfrac{e^2}{4\pi\epsilon_0 r}\right) = -2.67\times10^{-17}\text{ J} = -166.9\text{ eV}$.

(d) $E_\infty = -[-166.9\text{ eV} + 83.5\text{ eV}] = 83.4\text{ eV}$, which is only off by about 5% from the real value of 79.0 eV.

EVALUATE: The ground state energy of helium in this model is $K + U = -83.4$ eV. The ground state energy of He^+ is $4(-13.6\text{ eV}) = -54.4$ eV. Therefore, the energy required to remove one electron from helium in this model is $-(-83.4\text{ eV} + 54.4\text{ eV}) = 29.0$ eV. The experimental value for this quantity is 24.6 eV.

41.70. IDENTIFY and **SET UP:** For the Bohr hydrogen model, $r = a_0 n^2$.

EXECUTE: Using $r = a_0 n^2$ gives 1×10^{-6} m = 5.29×10^{-11} m, so $n = 137 \approx 140$, which makes choice (a) the correct one.

EVALUATE: The energy of an electron in this state would be only $E_{140} = (-13.6\text{ eV})/137^2 = -7.25\times10^{-4}$ eV, which is very small compared to ground-state hydrogen.

41.71. IDENTIFY and **SET UP:** Particle density is the number particles divided by the volume they occupy. The distance between particles is 10 times their size, which is 20 μm.

EXECUTE: Think of each atom as being in a cubical box that is 20 μm on each side. The particle density is (1 atom)/(20 μm)^3 = (1 atom)/(20 $\times10^{-4}$ cm)^3 = 1.25 $\times10^8$ atoms/cm^3 $\approx 10^8$ atoms/cm^3, choice (b).

EVALUATE: For rubidium, with 85 nucleons, the mass density ρ of these atoms would be $\rho = (85)(1.67\times10^{-24}\text{ g})(10^{8}\text{ atoms/cm}^3) = 1.4\times10^{-14}\text{ g/cm}^3$. Ordinary rubidium has a density of 1.53 g/cm^3, so these Rydberg atoms are much farther apart than rubidium atoms under normal conditions.

41.72. **IDENTIFY** and **SET UP:** $L = \sqrt{l(l+1)}\hbar.$ For this state, $n = 100$ and $l = 2$.

EXECUTE: $L = \sqrt{l(l+1)}\hbar = \sqrt{2(2+1)}\hbar = \sqrt{6}\hbar.$ So choice (b) is correct.

EVALUATE: This is not the largest that L could be since l could be 99 for $n = 100$.

41.73. **IDENTIFY** and **SET UP:** $m_l = \pm l, \pm(l-1), \ldots, 0$. $m_s = \pm\frac{1}{2}$ for each m_l value.

EXECUTE: If $l = 2$, $m_l = -2, -1, 0, +1, +2$; and $m_s = \pm\frac{1}{2}$ for each of these states, so there are 10 possible states, which is choice (d).

EVALUATE: In the $n = 100$ state, there are 100 possible values of l, so there are many more additional states for these values of l.

42

MOLECULES AND CONDENSED MATTER

VP42.3.1. **IDENTIFY:** This problem involves the rotational energy of a molecule.

SET UP and **EXECUTE:** **(a)** We want the reduced mass. Use the given masses in the equation

$$m_r = \frac{m_1 m_2}{m_1 + m_2}.$$

The result is $m_r = 1.240 \times 10^{-26}$ kg.

(b) We want the moment of inertia. Use $r_0 = 0.1154$ nm and the result of part (a). The result is $I = m_r r_0^2 = 1.651 \times 10^{-46}\ \text{kg} \cdot \text{m}^2$.

(c) We want the energies of the rotational states $l = 0, 1, 2$.

$$E_l = l(l+1)\frac{\hbar^2}{2I}$$

$$E_0 = 0$$

$$E_1 = 1(1+1)\frac{\hbar^2}{2I} = 4.203 \times 10^{-4}\ \text{eV} = 0.4203\ \text{meV}.$$

$$E_2 = 2(2+1)\frac{\hbar^2}{2I} = 1.261 \times 10^{-3}\ \text{eV} = 1.261\ \text{meV}.$$

EVALUATE: Note that molecular rotational energies are of the order of *milli*electron-volts, whereas energy states for electrons in atoms are around a few eV.

VP42.3.2. **IDENTIFY:** We are dealing with the rotational energy levels of a molecule.

SET UP: The following equations apply:

$$E_l = l(l+1)\frac{\hbar^2}{2I}, \quad m_r = \frac{m_1 m_2}{m_1 + m_2}, \quad I = m_r r_0^2.$$

EXECUTE: **(a)** We want the moment of inertia. Solve the E_l equation for I for the $l = 2$ state.

$$I = \frac{3\hbar^2}{E_2} = \frac{3\hbar^2}{7.90\ \text{meV}} = 2.64 \times 10^{-47}\ \text{kg} \cdot \text{m}^2.$$

(b) We want the reduced mass. Use the two given masses in the equation for m_r, giving

$$m_r = 1.627 \times 10^{-27}\ \text{kg}.$$

(c) We want the distance r_0 between the two nuclei. Solve $I = m_r r_0^2$ for r_0 and use the results of parts (a) and (b). This gives

$$r_0 = \sqrt{I/m_r} = 0.127\ \text{nm}.$$

EVALUATE: Note that the chlorine has only a small effect on the reduced mass which is essentially the mass of the hydrogen atom.

VP42.3.3. **IDENTIFY:** This problem is about the rotational energy levels of the SiO molecule.

SET UP: The following equations apply:

$$E_l = l(l+1)\frac{\hbar^2}{2I},\quad m_{\rm r} = \frac{m_1 m_2}{m_1+m_2},\quad I = m_{\rm r} r_0^2.$$

EXECUTE: **(a)** We want I. The energy of the emitted photon is equal to the energy difference between the $l = 0$ and $l = 1$ rotational levels. The photon energy is $E = hc/\lambda$. Therefore

$$E_1 - E_0 = 1(1+1)\frac{\hbar^2}{2I} - 0 = \frac{\hbar^2}{I}$$

Solving for I gives

$$I = \frac{\hbar\lambda}{2\pi c} = \frac{\hbar(6.882\text{ mm})}{2\pi c} = 3.853\times10^{-46}\text{ kg}\cdot\text{m}^2.$$

(b) We want the reduced mass. Use the given masses.

$$m_{\rm r} = \frac{m_1 m_2}{m_1+m_2} = 1.690\times10^{-26}\text{ kg}.$$

(c) We want r_0. Solve $I = m_{\rm r} r_0^2$ for r_0 and use the answers from parts (a) and (b), which gives r_0 = 0.1510 nm.

EVALUATE: The result in part (c) is quite reasonable for atomic distances in molecules.

VP42.3.4. **IDENTIFY:** This problem involves the vibrational and rotational energy levels in the CO molecule.

SET UP: When the molecule makes a transition to a lower energy state, the energy $E_{\rm ph}$ of the emitted photon is equal to the *magnitude* of the energy difference between the two states. Using Eq. (42.9) this photon energy is

$$E_{\rm ph} = l_1(l_1+1)\frac{\hbar^2}{2I} + \left(n_1+\frac{1}{2}\right)\hbar\omega - \left[l_2(l_2+1)\frac{\hbar^2}{2I} + \left(n_2+\frac{1}{2}\right)\hbar\omega\right]$$

$$E_{\rm ph} = \left[l_1(l_1+1) - l_2(l_2+1)\right]\frac{\hbar^2}{2I} + (n_1-n_2)\hbar\omega$$

$n_1 - n_2 = +1$. Using this fact and some results from Example 42.3, we have

$$(n_1-n_2)\hbar\omega = 0.2690\text{ eV},\quad \frac{\hbar^2}{2I} = 0.2395\text{ meV}$$

The photon energy is therefore given by

$$E_{\rm ph} = \left[l_1(l_1+1) - l_2(l_2+1)\right](0.2395\text{ meV}) + 0.2690\text{ eV}$$

EXECUTE: **(a)** Initial state is $l_1 = 3$. $\Delta l = -1$, so $l_2 = 2$.

$3 \to 2$ transition:

$$E_{\rm ph} = \left[3(3+1) - 2(2+1)\right](0.2395\text{ meV}) + 0.2690\text{ eV} = 1.4370\text{ meV} + 0.2690\text{ eV} = 0.270437\text{ eV}.$$

$$f = E_{\rm ph}/h = (0.270437\text{ eV})/h = 6.535\times10^{13}\text{ Hz}.$$

$$\lambda = c/f = 4.585\ \mu\text{m}.$$

(b) Initial state is $l_1 = 2$. $\Delta l = -1$, so $l_2 = 1$.

$2 \to 1$ transition:

$$E_{\rm ph} = \left[2(2+1) - 1(1+1)\right](0.2395\text{ meV}) + 0.2690\text{ eV} = 0.9580\text{ meV} + 0.2690\text{ eV} - 0.269958\text{ eV}$$

$$f = E_{\rm ph}/h = (0.269958\text{ eV})/h = 6.538\times10^{13}\text{ Hz}.$$

$$\lambda = c/f = 4.593\ \mu\text{m}.$$

EVALUATE: The wavelengths are very close together because the energy differences between states are very small since they are due only to *rotational* transitions which are low energy.

VP42.7.1. **IDENTIFY:** This problem involves the Fermi-Dirac distribution.

SET UP: Eq. (42.16) gives the probability $f(E)$ that a given energy state is occupied. The target variable is the energy for each probability. Solve for E in each case.

EXECUTE: **(a)** $f(E) = 0.33$. Solve for E.

$$0.33 = \frac{1}{e^{(E-E_\text{F})/kT}+1}$$

Separate the exponential and use logarithms, giving

$$(E - E_\text{F})/kT = \ln 2.02$$

$$E = E_\text{F} + 0.71kT.$$

(b) $f(E) = 0.90$. Follow the same procedure using 0.90 instead of 0.33, giving $E = E_\text{F} - 2.2kT$.

EVALUATE: If $E = E_\text{F}$, $f(E) = 0.50$, for $f(E) > 0.50$, $E < E_\text{F}$, and for $f(E) < 0.50$, $E > E_\text{F}$. Our results are consistent with these conditions.

VP42.7.2. **IDENTIFY:** This problem involves the Fermi-Dirac distribution.

SET UP: Eq. (42.16) gives the probability $f(E)$ that a given energy state is occupied. The target variable is the probability for each specified energy.

EXECUTE: **(a)** $E = E_\text{F} - 0.0250$ eV. Using Eq. (42.16) gives

$$f(E) = \frac{1}{e^{(E_\text{F}-0.0250\text{ eV}-E_\text{F})/kT}+1}$$

The exponent of e is $(0.0250\text{ eV})/kT = 0.9902$, so $f(E) = 1/(e^{-0.9902} + 1) = 0.729$.

(b) $E = E_\text{F} + 0.0400$ eV. Using Eq. (42.16) and following the same procedure gives $f(E) = 1/(e^{1.5843} + 1) = 0.170$.

(c) $E = E_\text{F} + 0.100$ eV. Using the same procedure gives $f(E) = 0.0187$.

EVALUATE: The probability decreases as E increases above the Fermi energy.

VP42.7.3. **IDENTIFY:** This problem involves the Fermi energy and the density of states.

SET UP and **EXECUTE:** **(a)** We want the Fermi energy at absolute zero. Using Eq. (42.19) with N/V given in the problem, we get

$$E_\text{F0} = \frac{3^{2/3}\pi^{4/3}\hbar^2}{2m}\left(\frac{N}{V}\right)^{2/3} = 5.5\text{ eV}.$$

(b) The speed is the target variable. The kinetic energy K is equal to the Fermi energy. Solve $K = E_\text{F}$ for v and use the result from part (a).

$$v = \sqrt{\frac{2E_\text{F}}{m}} = 1.4\times10^6\text{ m/s}.$$

(c) The target variable is the density of states. Use Eq. (42.15) with $V = 1.0\text{ cm}^3$ and $E = 5.5$ eV from part (a). The result is

$$g(E) = \frac{(2m)^{3/2}V}{2\pi^2\hbar^3}E^{1/2} = 9.9\times10^{40}\text{ states/J} = 1.6\times10^{22}\text{ states/eV}.$$

EVALUATE: The electron speeds are not great enough to require the use of special relativity.

VP42.7.4. **IDENTIFY:** This problem deals with the Fermi energy.

SET UP: From the previous problem we have $E_\text{F0} = 5.5$ eV. The target variable is the electron energy for the given probabilities.

EXECUTE: **(a)** $f(E) = 0.92$. Solve Eq. (42.16) for E using logarithms.

$$0.92 = \frac{1}{e^{(E-E_\text{F})/kT}+1}$$

$$E - E_\text{F} = kT\ln(0.08696)$$

$$E = 5.4\text{ eV}.$$

(b) $f(E) = 1.0 \times 10^{-4}$. Use the same procedure as in part (a) except $f(E) = 0.00010$, which gives $E = 5.7$ eV.

EVALUATE: Our results are consistent with problem VP42.7.1. When $E > E_F$, $f(E) < 0.50$, and when $E < E_F$, $f(E) > 0.50$.

VP42.9.1. **IDENTIFY:** This problem is about the Fermi energy and the band gap in a semiconductor.

SET UP and **EXECUTE:** For an electron at the bottom of the conduction band, $E = E_F + E_g/2$, so $E - E_F = E_g/2$. The target variable is the probability $f(E)$. Use Eq. (42.16) for $f(E)$.

(a) $E_g = 0.500$ eV. $(E - E_F)/kT = E_g/2kT = (0.500 \text{ eV})/2kT = 10.18$. Eq. (42.16) gives $f(E) = 1/(e^{10.18} + 1) = 3.79 \times 10^{-5}$.

(b) $E_g = 1.50$ eV. $(E - E_F)/kT = E_g/2kT = (1.50 \text{ eV})/2kT = 30.54$. Eq. (42.16) gives $f(E) = 1/(e^{30.54} + 1) = 5.46 \times 10^{-14}$.

EVALUATE: The probability decreases as the gap widens.

VP42.9.2. **IDENTIFY:** This problem is about the band gap in a semiconductor.

SET UP: $E = E_F + E_g/2$, so $E - E_F = E_g/2$. The target variable is the probability $f(E)$. Use Eq. (42.16) for $f(E)$. We want the ratio of the probabilities at different temperatures.

EXECUTE: **(a)** $E_g = 0.400$ eV. <u>At 315 K</u>: $E_g/2kT = (0.400 \text{ eV})/[2k(315 \text{ K})] = 7.3682$. $f(E)_{315} = 1/(e^{7.3682} + 1) = 6.3058 \times 10^{-4}$.

<u>At 295 K</u>: The exponent is 7.8677, so $f(E) = 1/(e^{7.8677} + 1) = 3.8290 \times 10^{-4}$.

Now take the ratio of the probabilities using the results we just found. This gives

$$\frac{f(E)_{315}}{f(E)_{295}} = \frac{6.3058\times10^{-4}}{3.8290\times10^{-4}} = 1.65.$$

(b) $E_g = 0.800$ eV. Use the same procedure as for part (a). <u>At 315 K</u>: $E_g/2kT = 14.7364$ which gives $f(E) = 3.98165 \times 10^{-7}$.

<u>At 295 K</u>: $E_g/2kT = 15.7354$ which gives $f(E) = 1.46623 \times 10^{-7}$.

$$\frac{f(E)_{315}}{f(E)_{295}} = \frac{3.98165\times10^{-7}}{1.46623\times10^{-7}} = 2.72.$$

EVALUATE: At $T = 315$ K the probability is greater than at 295 K, which is in agreement with Example 42.9.

VP42.9.3. **IDENTIFY:** We are dealing with the energy gap in a semiconductor.

SET UP: The target variable is the width of the energy gap E_g at different temperatures. Combining $E - E_F = E_g/2$ with Eq. (42.16) gives

$$f(E) = \frac{1}{e^{E_g/2kT} + 1}$$

Solve this equation for E_g using logarithms.

$$E_g = 2kT \ln\left(1 + \frac{1}{f(E)}\right) = 2kT \ln(527.32).$$

EXECUTE: **(a)** $T = 305$ K. Using this temperature in the equation we just derived gives $E_g = 0.329$ eV.

(b) $T = 325$ K. Using the same procedure gives $E_g = 0.351$ eV.

EVALUATE: As the temperature increases, the gap width also increases.

VP42.9.4. **IDENTIFY:** We are dealing with the energy gap in a semiconductor.

SET UP: The target variable is the probability at different temperatures. Figure VP42.9.4 helps to visualize how the various quantities are related. In this case, $E = E_F + E_g/4$. Therefore $E - E_F = E_g/4 = (0.300 \text{ eV})/4 = 0.0750$ eV and $(E - E_F)/kT = (0.0750 \text{ eV})/kT = (870.37 \text{ K})/T$.

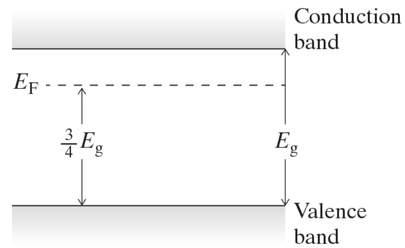

Figure VP42.9.4

EXECUTE: Use Eq. (42.16).

(a) $T = 275$ K. $(E - E_F)/kT = (870.37\text{ K})/T = (870.37\text{ K})/(275\text{ K}) = 3.1650$. Therefore

$$f(E) = \frac{1}{e^{3.1650}+1} = 0.0405.$$

(b) $T = 325$ K. $(E - E_F)/kT = (870.37\text{ K})/T = (870.37\text{ K})/(325\text{ K}) = 2.67806$. Therefore

$$f(E) = \frac{1}{e^{2.67806}+1} = 0.0643.$$

EVALUATE: As the temperature increases, so does the probability of finding electrons in the conduction band.

42.1. IDENTIFY and **SET UP:** $U = \frac{1}{4\pi\epsilon_0}\frac{q_1q_2}{r}$. The binding energy of the molecule is equal to U plus the ionization energy of K minus the electron affinity of Br.

EXECUTE: **(a)** $U = -\frac{1}{4\pi\epsilon_0}\frac{e^2}{r} = -5.0\text{ eV}$.

(b) $-5.0\text{ eV} + (4.3\text{ eV} - 3.5\text{ eV}) = -4.2\text{ eV}$.

EVALUATE: We expect the magnitude of the binding energy to be somewhat less than this estimate. At this separation the two ions don't behave exactly like point charges and U is smaller in magnitude than our estimate. The experimental value for the binding energy is -4.0 eV, which is smaller in magnitude than our estimate.

42.2. IDENTIFY: The energy decrease of the molecule or atom is equal to the energy of the emitted photon. From this energy, we can calculate the wavelength of the photon.

SET UP: $\Delta E = \frac{hc}{\lambda}$. Use Figure 32.4 in the textbook to find out the region of the electromagnetic spectrum in which each wavelength lies.

(a) EXECUTE: $\lambda = \frac{hc}{\Delta E} = \frac{(4.136\times10^{-15}\text{ eV}\cdot\text{s})(3.00\times10^{8}\text{ m/s})}{0.198\text{ eV}} = 6.26\ \mu\text{m}$.

EVALUATE: This radiation is in the infrared.

(b) EXECUTE: $\lambda = \frac{hc}{\Delta E} = \frac{(4.136\times10^{-15}\text{ eV}\cdot\text{s})(3.00\times10^{8}\text{ m/s})}{7.80\text{ eV}} = 159\text{ nm}$.

EVALUATE: This radiation is in the ultraviolet.

(c) EXECUTE: $\lambda = \frac{hc}{\Delta E} = \frac{(4.136\times10^{-15}\text{ eV}\cdot\text{s})(3.00\times10^{8}\text{ m/s})}{4.80\times10^{-3}\text{ eV}} = 0.258\text{ mm}$.

EVALUATE: This radiation is in the microwave region.

42.3. **IDENTIFY:** The energy of the photon is equal to the energy difference between the $l=1$ and $l=2$ states. This energy determines its wavelength.

SET UP: The reduced mass of the molecule is $m_r = \dfrac{m_H m_H}{m_H + m_H} = \frac{1}{2}m_H$, its moment of inertia is $I = m_r r_0^2$, the photon energy is $\Delta E = \dfrac{hc}{\lambda}$, and the energy of the state l is $E_l = l(l+1)\dfrac{\hbar^2}{2I}$.

EXECUTE: $I = m_r r_0^2 = \frac{1}{2}(1.67\times10^{-27}\text{ kg})(0.074\times10^{-9}\text{ m})^2 = 4.57\times10^{-48}\text{ kg}\cdot\text{m}^2$. Using $E_l = l(l+1)\dfrac{\hbar^2}{2I}$, the energy levels are

$E_2 = 6\dfrac{\hbar^2}{2I} = 6\dfrac{(1.055\times10^{-34}\text{ J}\cdot\text{s})^2}{2(4.57\times10^{-48}\text{ kg}\cdot\text{m}^2)} = 6(1.218\times10^{-21}\text{ J}) = 7.307\times10^{-21}\text{ J}$ and

$E_1 = 2\dfrac{\hbar^2}{2I} = 2(1.218\times10^{-21}\text{ J}) = 2.436\times10^{-21}\text{ J}$. $\Delta E = E_2 - E_1 = 4.87\times10^{-21}\text{ J}$. Using $\Delta E = \dfrac{hc}{\lambda}$ gives

$$\lambda = \frac{hc}{\Delta E} = \frac{(6.626\times10^{-34}\text{ J}\cdot\text{s})(2.998\times10^8\text{ m/s})}{4.871\times10^{-21}\text{ J}} = 4.08\times10^{-5}\text{ m} = 40.8\ \mu\text{m}.$$

EVALUATE: This wavelength is much longer than that of visible light.

42.4. **IDENTIFY:** The energy absorbed by the photon is equal to the energy difference between the two rotational states.

SET UP: The rotational energy of a molecule is $E_l = l(l+1)\dfrac{\hbar^2}{2I}$ and the energy of the photon is the energy difference ΔE between the states, so $\Delta E = hc/\lambda$. The transition is from the $l = 3$ state to the $l = 4$ state.

EXECUTE: Using the rotational energy formula, the energy difference between the two states is

$$\Delta E = E_4 - E_3 = 4(4+1)\frac{\hbar^2}{2I} - 3(3+1)\frac{\hbar^2}{2I} = 4\frac{\hbar^2}{I}.$$

This is the energy absorbed by the photon, so $\Delta E = hc/\lambda$ gives $hc/\lambda = 4\hbar^2/I$. Solving for λ gives $\lambda = \pi^2 Ic/h = \pi^2(4.6\times10^{-48}\text{ kg}\cdot\text{m}^2)(3.00\times10^8\text{ m/s})/(6.626\times10^{-34}\text{ J}\cdot\text{s}) = 2.05\times10^{-5}\text{ m} = 20.6\ \mu\text{m}$, which rounds to 21 μm.

EVALUATE: Rotational energy changes are much less than transitions between n-shells, so the wavelengths involved are much longer for rotational transitions.

42.5. **IDENTIFY:** The energy given to the photon comes from a transition between rotational states.

SET UP: The rotational energy of a molecule is $E = l(l+1)\dfrac{\hbar^2}{2I}$ and the energy of the photon is $E = hc/\lambda$.

EXECUTE: Use the energy formula, the energy difference between the $l = 3$ and $l = 1$ rotational levels of the molecule is $\Delta E = \dfrac{\hbar^2}{2I}[3(3+1) - 1(1+1)] = \dfrac{5\hbar^2}{I}$. Since $\Delta E = hc/\lambda$, we get $hc/\lambda = 5\hbar^2/I$. Solving for I gives

$$I = \frac{5\hbar\lambda}{2\pi c} = \frac{5(1.055\times10^{-34}\text{ J}\cdot\text{s})(1.780\text{ nm})}{2\pi(3.00\times10^8\text{ m/s})} = 4.981\times10^{-52}\text{ kg}\cdot\text{m}^2.$$

Using $I = m_r r_0^2$, we can solve for r_0:

$$r_0 = \sqrt{\frac{I(m_N + m_H)}{m_N m_H}} = \sqrt{\frac{(4.981\times10^{-52}\text{ kg}\cdot\text{m}^2)(2.33\times10^{-26}\text{ kg} + 1.67\times10^{-27}\text{ kg})}{(2.33\times10^{-26}\text{ kg})(1.67\times10^{-27}\text{ kg})}} = 5.65\times10^{-13}\text{ m}.$$

EVALUATE: This separation is much smaller than the diameter of a typical atom and is not very realistic. But we are treating a *hypothetical* NH molecule.

42.6. **IDENTIFY:** $I = m_1 r_1^2 + m_2 r_2^2$. Since the two atoms are identical, the center of mass is midway between them.

SET UP: Each atom has a mass m and is at a distance $L/2$ from the center of mass.

EXECUTE: The moment of inertia is $2(m)(L/2)^2 = mL^2/2 = 2.21\times10^{-44}\ \text{kg}\cdot\text{m}^2$.

EVALUATE: $r_0 = L$ and $m_r = m/2$, so $I = m_r r_0^2$ gives the same result.

42.7. **IDENTIFY** and **SET UP:** Set $K = E_1$ from Example 42.2. Use $K = \frac{1}{2}I\omega^2$ to solve for ω and $v = r\omega$ to solve for v.

EXECUTE: **(a)** From Example 42.2, $E_1 = 0.479\ \text{meV} = 7.674\times10^{-23}\ \text{J}$ and $I = 1.449\times10^{-46}\ \text{kg}\cdot\text{m}^2$.
$K = \frac{1}{2}I\omega^2$ and $K = E$ gives $\omega = \sqrt{2E_1/I} = 1.03\times10^{12}\ \text{rad/s}$.

(b) $v_1 = r_1\omega_1 = (0.0644\times10^{-9}\ \text{m})(1.03\times10^{12}\ \text{rad/s}) = 66.3\ \text{m/s}$ (carbon).

$v_2 = r_2\omega_2 = (0.0484\times10^{-9}\ \text{m})(1.03\times10^{12}\ \text{rad/s}) = 49.8\ \text{m/s}$ (oxygen).

(c) $T = 2\pi/\omega = 6.10\times10^{-12}\ \text{s}$.

EVALUATE: Even for fast rotation rates, $v \ll c$.

42.8. **IDENTIFY:** Find ΔE for the transition and compute λ from $\Delta E = hc/\lambda$.

SET UP: From Example 42.2, $E_l = l(l+1)\dfrac{\hbar^2}{2I}$, with $\dfrac{\hbar^2}{2I} = 0.2395\times10^{-3}\ \text{eV}$. $\Delta E = 0.2690\ \text{eV}$ is the spacing between vibrational levels. Thus $E_n = (n+\frac{1}{2})\hbar\omega$, with $\hbar\omega = 0.2690\ \text{eV}$. The total vibrational and rotational energy is $E = E_n + E_l = (n+\frac{1}{2})\hbar\omega + l(l+1)\dfrac{\hbar^2}{2I}$.

EXECUTE: **(a)** $n = 0 \to n = 1$ and $l = 2 \to l = 3$.

For $n = 0,\ l = 2,\ E_i = \frac{1}{2}\hbar\omega + 6\left(\dfrac{\hbar^2}{2I}\right)$.

For $n = 1,\ l = 3,\ E_f = \frac{3}{2}\hbar\omega + 12\left(\dfrac{\hbar^2}{2I}\right)$.

$$\Delta E = E_f - E_i = \hbar\omega + 6\left(\frac{\hbar^2}{2I}\right) = 0.2690\ \text{eV} + 6(0.2395\times10^{-3}\ \text{eV}) = 0.2704\ \text{eV}.$$

$$\frac{hc}{\lambda} = \Delta E \text{ so } \lambda = \frac{hc}{\Delta E} = \frac{(4.136\times10^{-15}\ \text{eV}\cdot\text{s})(2.998\times10^{8}\ \text{m/s})}{0.2704\ \text{eV}} = 4.586\times10^{-6}\ \text{m} = 4.586\ \mu\text{m}.$$

(b) $n = 0 \to n = 1$ and $l = 3 \to l = 2$.

For $n = 0,\ l = 3,\ E_i = \frac{1}{2}\hbar\omega + 12\left(\dfrac{\hbar^2}{2I}\right)$.

For $n = 1,\ l = 2,\ E_f = \frac{3}{2}\hbar\omega + 6\left(\dfrac{\hbar^2}{2I}\right)$.

$$\Delta E = E_f - E_i = \hbar\omega - 6\left(\frac{\hbar^2}{2I}\right) = 0.2690\ \text{eV} - 6(0.2395\times10^{-3}\ \text{eV}) = 0.2676\ \text{eV}.$$

$$\lambda = \frac{hc}{\Delta E} = \frac{(4.136\times10^{-15}\ \text{eV}\cdot\text{s})(2.998\times10^{8}\ \text{m/s})}{0.2676\ \text{eV}} = 4.634\times10^{-6}\ \text{m} = 4.634\ \mu\text{m}.$$

(c) $n=0 \to n=1$ and $l=4 \to l=3$.

For $n=0, l=4,\ E_i = \frac{1}{2}\hbar\omega + 20\left(\frac{\hbar^2}{2I}\right)$.

For $n=1, l=3,\ E_f = \frac{3}{2}\hbar\omega + 12\left(\frac{\hbar^2}{2I}\right)$.

$$\Delta E = E_f - E_i = \hbar\omega - 8\left(\frac{\hbar^2}{2I}\right) = 0.2690\ \text{eV} - 8(0.2395\times10^{-3}\ \text{eV}) = 0.2671\ \text{eV}.$$

$$\lambda = \frac{hc}{\Delta E} = \frac{(4.136\times10^{-15}\ \text{eV}\cdot\text{s})(2.998\times10^{8}\ \text{m/s})}{0.2671\ \text{eV}} = 4.643\times10^{-6}\ \text{m} = 4.643\,\mu\text{m}.$$

EVALUATE: All three transitions are for $n=0 \to n=1$. The spacing between vibrational levels is larger than the spacing between rotational levels, so the difference in λ for the various rotational transitions is small. When the transition is to a larger *l*, $\Delta E > \hbar\omega$ and when the transition is to a smaller *l*, $\Delta E < \hbar\omega$.

42.9. IDENTIFY and SET UP: The energy of a rotational level with quantum number *l* is $E_l = l(l+1)\hbar^2/2I$. $I = m_r r^2$, with the reduced mass m_r given by $m_r = \dfrac{m_1 m_2}{m_1+m_2}$. Calculate *I* and ΔE and then use $\Delta E = hc/\lambda$ to find λ.

EXECUTE: (a) $m_r = \dfrac{m_1 m_2}{m_1+m_2} = \dfrac{m_{Li} m_H}{m_{Li}+m_H} = \dfrac{(1.17\times10^{-26}\ \text{kg})(1.67\times10^{-27}\ \text{kg})}{1.17\times10^{-26}\ \text{kg} + 1.67\times10^{-27}\ \text{kg}} = 1.461\times10^{-27}\ \text{kg}.$

$I = m_r r^2 = (1.461\times10^{-27}\ \text{kg})(0.159\times10^{-9}\ \text{m})^2 = 3.694\times10^{-47}\ \text{kg}\cdot\text{m}^2.$

$l=3: E = 3(4)\left(\frac{\hbar^2}{2I}\right) = 6\left(\frac{\hbar^2}{I}\right).$

$l=4: E = 4(5)\left(\frac{\hbar^2}{2I}\right) = 10\left(\frac{\hbar^2}{I}\right).$

$$\Delta E = E_4 - E_3 = 4\left(\frac{\hbar^2}{I}\right) = 4\left(\frac{(1.055\times10^{-34}\ \text{J}\cdot\text{s})^2}{3.694\times10^{-47}\ \text{kg}\cdot\text{m}^2}\right) = 1.20\times10^{-21}\ \text{J} = 7.49\times10^{-3}\ \text{eV}.$$

(b) $\Delta E = hc/\lambda$, so $\lambda = \dfrac{hc}{\Delta E} = \dfrac{(4.136\times10^{-15}\ \text{eV})(2.998\times10^{8}\ \text{m/s})}{7.49\times10^{-3}\ \text{eV}} = 166\ \mu\text{m}.$

EVALUATE: LiH has a smaller reduced mass than CO and λ is somewhat smaller here than the λ calculated for CO in Example 42.2.

42.10. IDENTIFY: For a $n \to n-1$ vibrational transition, $\Delta E = \hbar\sqrt{\dfrac{k'}{m_r}}$. ΔE is related to λ of the photon by $\Delta E = \dfrac{hc}{\lambda}$.

SET UP: $m_r = \dfrac{m_{Na} m_{Cl}}{m_{Na}+m_{Cl}}$.

EXECUTE: $\Delta E = \dfrac{hc}{\lambda} = \hbar\sqrt{k'/m_r}$, and solving for k', $k' = \left(\dfrac{2\pi c}{\lambda}\right)^2 m_r = 205\ \text{N/m}.$

EVALUATE: The value of k' we calculated for NaCl is comparable to that of a fairly stiff lab spring.

42.11. **IDENTIFY:** The vibrational energy of the molecule is related to its force constant and reduced mass, while the rotational energy depends on its moment of inertia, which in turn depends on the reduced mass.

SET UP: The vibrational energy is $E_n = (n+\frac{1}{2})\hbar\omega = (n+\frac{1}{2})\hbar\sqrt{\frac{k'}{m_r}}$ and the rotational energy is $E_l = l(l+1)\frac{\hbar^2}{2I}$.

EXECUTE: For a vibrational transition, we have $\Delta E_v = \hbar\sqrt{\frac{k'}{m_r}}$, so we first need to find m_r. The energy for a rotational transition is $\Delta E_R = \frac{\hbar^2}{2I}[2(2+1)-1(1+1)] = \frac{2\hbar^2}{I}$. Solving for I and using the fact that $I = m_r r_0^2$, we have $m_r r_0^2 = \frac{2\hbar^2}{\Delta E_R}$, which gives

$$m_r = \frac{2\hbar^2}{r_0^2\Delta E_R} = \frac{2(1.055\times10^{-34}\ \text{J}\cdot\text{s})(6.583\times10^{-16}\ \text{eV}\cdot\text{s})}{(0.8860\times10^{-9}\ \text{m})^2(8.841\times10^{-4}\ \text{eV})} = 2.0014\times10^{-28}\ \text{kg}.$$

Now look at the vibrational transition to find the force constant.

$$\Delta E_v = \hbar\sqrt{\frac{k'}{m_r}} \Rightarrow k' = \frac{m_r(\Delta E_v)^2}{\hbar^2} = \frac{(2.0014\times10^{-28}\ \text{kg})(0.2560\ \text{eV})^2}{(6.583\times10^{-16}\ \text{eV}\cdot\text{s})^2} = 30.27\ \text{N/m}.$$

EVALUATE: This would be a rather weak spring in the laboratory.

42.12. **IDENTIFY** and **SET UP:** For an average spacing a, the density is $\rho = m/a^3$, where m is the average of the ionic masses.

EXECUTE: **(a)** $a^3 = \frac{m}{\rho} = \frac{(6.49\times10^{-26}\ \text{kg} + 1.33\times10^{-25}\ \text{kg})/2}{(2.75\times10^3\ \text{kg/m}^3)} = 3.60\times10^{-29}\ \text{m}^3$, and

$a = 3.30\times10^{-10}\ \text{m} = 0.330\ \text{nm}.$

EVALUATE: **(b)** Exercise 42.15 says that the average spacing for NaCl is 0.282 nm. The larger (higher atomic number) atoms have the larger spacing.

42.13. **IDENTIFY** and **SET UP:** Find the volume occupied by each atom. The density is the average mass of Na and Cl divided by this volume.

EXECUTE: Each atom occupies a cube with side length 0.282 nm. Therefore, the volume occupied by each atom is $V = (0.282\times10^{-9}\ \text{m})^3 = 2.24\times10^{-29}\ \text{m}^3$. In NaCl there are equal numbers of Na and Cl atoms, so the average mass of the atoms in the crystal is

$$m = \tfrac{1}{2}(m_{\text{Na}} + m_{\text{Cl}}) = \tfrac{1}{2}(3.82\times10^{-26}\ \text{kg} + 5.89\times10^{-26}\ \text{kg}) = 4.855\times10^{-26}\ \text{kg}.$$

The density then is $\rho = \frac{m}{V} = \frac{4.855\times10^{-26}\ \text{kg}}{2.24\times10^{-29}\ \text{m}^3} = 2.17\times10^3\ \text{kg/m}^3.$

EVALUATE: The density of water is $1.00\times10^3\ \text{kg/m}^3$, so our result is reasonable.

42.14. **IDENTIFY** and **SET UP:** $\Delta E = \frac{hc}{\lambda}$, where ΔE is the band gap.

EXECUTE: **(a)** $\lambda = \frac{hc}{\Delta E} = 2.27\times10^{-7}\ \text{m} = 227\ \text{nm}$, in the ultraviolet.

EVALUATE: **(b)** Visible light lacks enough energy to excite the electrons into the conduction band, so visible light passes through the diamond unabsorbed.

(c) Impurities can lower the gap energy making it easier for the material to absorb shorter wavelength visible light. This allows longer wavelength visible light to pass through, giving the diamond color.

42.15. **IDENTIFY:** The energy gap is the energy of the maximum-wavelength photon.

SET UP: The energy difference is equal to the energy of the photon, so $\Delta E = hc/\lambda$.

EXECUTE: **(a)** Using the photon wavelength to find the energy difference gives

$$\Delta E = hc/\lambda = (4.136\times10^{-15}\text{ eV}\cdot\text{s})(3.00\times10^{8}\text{ m/s})/(1.11\times10^{-6}\text{ m}) = 1.12\text{ eV}.$$

(b) A wavelength of $1.11\ \mu\text{m} = 1110\text{ nm}$ is in the infrared, shorter than that of visible light.

EVALUATE: Since visible photons have more than enough energy to excite electrons from the valence to the conduction band, visible light will be absorbed, which makes silicon opaque.

42.16. **IDENTIFY** and **SET UP:** The energy ΔE deposited when a photon with wavelength λ is absorbed is $\Delta E = \dfrac{hc}{\lambda}$.

EXECUTE: $\Delta E = \dfrac{hc}{\lambda} = \dfrac{(6.63\times10^{-34}\text{ J}\cdot\text{s})(3.00\times10^{8}\text{ m/s})}{9.31\times10^{-13}\text{ m}} = 2.14\times10^{-13}\text{ J} = 1.34\times10^{6}\text{ eV}.$ So the number of electrons that can be excited to the conduction band is $n = \dfrac{1.34\times10^{6}\text{ eV}}{1.12\text{ eV}} = 1.20\times10^{6}$ electrons.

EVALUATE: A photon of wavelength

$\lambda = \dfrac{hc}{\Delta E} = \dfrac{(4.13\times10^{-15}\text{ eV}\cdot\text{s})(3.00\times10^{8}\text{ m/s})}{1.12\text{ eV}} = 1.11\times10^{-6}\text{ m} = 1110\text{ nm}$ can excite one electron. This photon is in the infrared.

42.17. **IDENTIFY:** The density of states is given by $g(E) = \dfrac{(2m)^{3/2}V}{2\pi^2\hbar^3}E^{1/2}$.

SET UP: $m = 9.11\times10^{-31}\text{ kg}$, the mass of an electron.

EXECUTE:

$$g(E) = \frac{(2m)^{3/2}V}{2\pi^2\hbar^3}E^{1/2} = \frac{[2(9.11\times10^{-31}\text{ kg})]^{3/2}(1.0\times10^{-6}\text{ m}^3)(5.0\text{ eV})^{1/2}(1.60\times10^{-19}\text{ J/eV})^{1/2}}{2\pi^2(1.054\times10^{-34}\text{ J}\cdot\text{s})^3}.$$

$g(E) = (9.5\times10^{40}\text{ states/J})(1.60\times10^{-19}\text{ J/eV}) = 1.5\times10^{22}\text{ states/eV}.$

EVALUATE: For a metal the density of states expressed as states/eV is very large.

42.18. **IDENTIFY:** At absolute zero, the average free-electron energy is $E_{\text{av}} = \dfrac{3}{5}E_{\text{F}}$. The speed v is related to E_{av} by $\frac{1}{2}mv^2 = E_{\text{av}}$.

SET UP: $k = 1.38\times10^{-23}\text{ J/K}$.

EXECUTE: **(a)** $E_{\text{av}} = \dfrac{3}{5}E_{\text{F}} = 1.94\text{ eV}$.

(b) $v = \sqrt{2E_{\text{av}}/m} = \sqrt{\dfrac{2(1.94\text{ eV})(1.60\times10^{-19}\text{ J/eV})}{9.11\times10^{-31}\text{ kg}}} = 8.25\times10^{5}\text{ m/s}.$

(c) $\dfrac{E_{\text{F}}}{k} = \dfrac{(3.23\text{ eV})(1.60\times10^{-19}\text{ J/eV})}{(1.38\times10^{-23}\text{ J/K})} = 3.74\times10^{4}\text{ K}.$

EVALUATE: The Fermi energy of sodium is less than that of copper. Therefore, the values of E_{av} and v we have calculated for sodium are less than those calculated for copper in Example 42.7.

42.19. **IDENTIFY:** This problem deals with the density of states $g(E)$.

SET UP: The original energy is 1.60 eV and we want to know the new energy. From Eq. (42.15) we see that $g(E)$ is proportional to the square root of E.

EXECUTE: **(a)** $g(E)$ is doubled. Since $g(E)$ is proportional to the square root of the energy, E must increase by a factor of 4 to double $g(E)$, so E = 4(1.60 eV) = 6.40 eV.

(b) $g(E)$ is halved. We need to decrease $g(E)$ by a factor of $\frac{1}{2}$, so E must decrease by a factor of $\frac{1}{4}$, so $E = (1.60\text{ eV})/4 = 0.400\text{ eV}$.

EVALUATE: A larger fractional change in E is required than the fractional change in $g(E)$.

42.20. **IDENTIFY:** This problem involves the Fermi-Dirac distribution.

SET UP: Eq. (42.16) gives this distribution. We know that $kT = 0.25E_F$ and we want the probability $f(E)$.

EXECUTE: **(a)** $E = 0.50E_F$. Using Eq. (42.16) gives

$$f(0.50E_F) = \frac{1}{e^{(0.50E_F - E_F)} + 1} = \frac{1}{e^{-2} + 1} = 0.88.$$

(b) $E = 1.50E_F$. Use the same procedure as in (a) with $E = 1.50E_F$. $f(1.50E_F) = 1/(e^2 + 1) = 0.12$.

EVALUATE: Our results agree with the curve for $kT = \frac{1}{4}E_F$ in Figure 42.23.

42.21. **IDENTIFY** and **SET UP:** The electron contribution to the molar heat capacity at constant volume of a metal is $C_V = \left(\dfrac{\pi^2 kT}{2E_F}\right)R$.

EXECUTE: **(a)** $C_V = \dfrac{\pi^2(1.381\times10^{-23}\text{ J/K})(300\text{ K})}{2(5.48\text{ eV})(1.602\times10^{-19}\text{ J/eV})}R = 0.0233R.$

(b) The electron contribution found in part (a) is $0.0233R = 0.194\text{ J/mol}\cdot\text{K}$. This is $0.194/25.3 = 7.67\times10^{-3} = 0.767\%$ of the total C_V.

EVALUATE: **(c)** Only a small fraction of C_V is due to the electrons. Most of C_V is due to the vibrational motion of the ions.

42.22. **IDENTIFY** and **SET UP:** The probability $f(E)$ that a state with energy E is occupied is given by the Fermi-Dirac distribution $f(E) = \dfrac{1}{e^{(E-E_F)/kT} + 1}$, where E_F is the Fermi energy. In this case, $E = 2E_F = 2(kT_F)$.

EXECUTE: $f(2E) = \dfrac{1}{e^{(2E_F - E_F)/kT_F} + 1} = \dfrac{1}{e^{E_F/kT_F} + 1} = \dfrac{1}{e^{kT_F/kT_F} + 1} = \dfrac{1}{e + 1} = 0.269.$

EVALUATE: A probability of $0.269 \approx 27\%$ is about 1 in 4. As E increases, the probability gets smaller.

42.23. **IDENTIFY:** The probability is given by the Fermi-Dirac distribution.

SET UP: The Fermi-Dirac distribution is $f(E) = \dfrac{1}{e^{(E-E_F)/kT} + 1}$.

EXECUTE: We calculate the value of $f(E)$, where $E = 8.520\text{ eV}$, $E_F = 8.500\text{ eV}$, $k = 1.38\times10^{-23}\text{ J/K} = 8.625\times10^{-5}\text{ eV/K}$, and $T = 20°\text{C} = 293\text{ K}$. The result is $f(E) = 0.312 = 31.2\%$.

EVALUATE: Since the energy is close to the Fermi energy, the probability is quite high that the state is occupied by an electron.

42.24. **IDENTIFY** and **SET UP:** Follow the procedure of Example 42.9. Evaluate $f(E) = \dfrac{1}{e^{(E-E_F)/kT} + 1}$ for $E - E_F = E_g/2$, where E_g is the band gap.

EXECUTE: **(a)** The probabilities are 1.78×10^{-7}, 2.37×10^{-6}, and 1.51×10^{-5}.

(b) It can be shown that the Fermi-Dirac distribution, $f(E) = \dfrac{1}{e^{(E-E_F)/kT} + 1}$, has the property that $f(E_F - E) = 1 - f(E)$, and so the probability that a state at the top of the valence band is occupied is the same as the probability that a state of the bottom of the conduction band is filled (this result depends on having the Fermi energy in the middle of the gap). Therefore, the probabilities at each T are the same as in part (a).

EVALUATE: The probabilities increase with temperature.

42.25. **IDENTIFY:** Use the Fermi-Dirac distribution $f(E) = \dfrac{1}{e^{(E-E_F)/kT}+1}$. Solve for $E-E_F$.

SET UP: $e^{(E-E_F)/kT} = \dfrac{1}{f(E)} - 1.$

The problem states that $f(E) = 4.4\times10^{-4}$ for E at the bottom of the conduction band.

EXECUTE: $e^{(E-E_F)/kT} = \dfrac{1}{4.4\times10^{-4}} - 1 = 2.272\times10^3.$

$E - E_F = kT\ln(2.272\times10^3) = (1.3807\times10^{-23}\text{ J/T})(300\text{ K})\ln(2.272\times10^3) = 3.201\times10^{-20}\text{ J} = 0.20\text{ eV}.$

$E_F = E - 0.20\text{ eV};$ the Fermi level is 0.20 eV below the bottom of the conduction band.

EVALUATE: The energy gap between the Fermi level and bottom of the conduction band is large compared to kT at $T = 300\text{ K}$ and as a result $f(E)$ is small.

42.26. **IDENTIFY:** The wavelength of the photon to be detected depends on its energy.

SET UP: $\Delta E = \dfrac{hc}{\lambda}.$

EXECUTE: **(a)** $\lambda = \dfrac{hc}{\Delta E} = \dfrac{(4.136\times10^{-15}\text{ eV}\cdot\text{s})(3.00\times10^8\text{ m/s})}{0.67\text{ eV}} = 1.9\ \mu\text{m}.$

(b) $\lambda = (1.9\ \mu\text{m})\left(\dfrac{0.67\text{ eV}}{1.12\text{ eV}}\right) = 1.1\ \mu\text{m}.$

EVALUATE: Both of these photons are in the infrared.

42.27. **IDENTIFY:** Knowing the saturation current of a *p-n* junction at a given temperature, we want to find the current at that temperature for various voltages.

SET UP: $I = I_S(e^{eV/kT} - 1).$

EXECUTE: **(a)** (i) For $V = 1.00\text{ mV},\ \dfrac{eV}{kT} = \dfrac{(1.602\times10^{-19}\text{ C})(1.00\times10^{-3}\text{ V})}{(1.381\times10^{-23}\text{ J/K})(290\text{ K})} = 0.0400.$

$I = (0.500\text{ mA})(e^{0.0400} - 1) = 0.0204\text{ mA}.$

(ii) For $V = -1.00\text{ mV},\ \dfrac{eV}{kT} = -0.0400.\ \ I = (0.500\text{ mA})(e^{-0.0400} - 1) = -0.0196\text{ mA}.$

(iii) For $V = 100\text{ mV},\ \dfrac{eV}{kT} = 4.00.\ \ I = (0.500\text{ mA})(e^{4.00} - 1) = 26.8\text{ mA}.$

(iv) For $V = -100\text{ mV},\ \dfrac{eV}{kT} = -4.00.\ \ I = (0.500\text{ mA})(e^{-4.00} - 1) = -0.491\text{ mA}.$

EVALUATE: **(b)** For small V, between ±1.00 mV, $R = V/I$ is approximately constant and the diode obeys Ohm's law to a good approximation. For larger V the deviation from Ohm's law is substantial.

42.28. **IDENTIFY:** The current depends on the voltage across the diode and its temperature, so the resistance also depends on these quantities.

SET UP: The current is $I = I_S\,(e^{eV/kT} - 1)$ and the resistance is $R = V/I$.

EXECUTE: **(a)** The resistance is $R = \dfrac{V}{I} = \dfrac{V}{I_s(e^{eV/kT} - 1)}$. The exponent is

$\dfrac{eV}{kT} = \dfrac{e(0.0850\text{ V})}{(8.625\times10^{-5}\text{ eV/K})(293\text{ K})} = 3.3635,$ giving $R = \dfrac{85.0\text{ mV}}{(0.950\text{ mA})(e^{3.3635} - 1)} = 3.21\ \Omega.$

(b) In this case, the exponent is $\dfrac{eV}{kT} = \dfrac{e(-0.050\text{ V})}{(8.625\times10^{-5}\text{ eV/K})(293\text{ K})} = -1.979$

which gives $R = \dfrac{-50.0\text{ mV}}{(0.950\text{ mA})(e^{-1.979}-1)} = 61.1\ \Omega.$

EVALUATE: Reversing the voltage can make a considerable change in the resistance of a diode.

42.29. **IDENTIFY** and **SET UP:** The voltage-current relation is given by $I = I_s(e^{eV/kT}-1)$. Use the current for $V = +15.0\text{ mV}$ to solve for the constant I_s.

EXECUTE: **(a)** Find $I_s: V = +15.0\times10^{-3}\text{ V}$ gives $I = 9.25\times10^{-3}\text{ A}$.

$$\frac{eV}{kT} = \frac{(1.602\times10^{-19}\text{ C})(15.0\times10^{-3}\text{ V})}{(1.381\times10^{-23}\text{ J/K})(300\text{ K})} = 0.5800.$$

$$I_s = \frac{I}{e^{eV/kT}-1} = \frac{9.25\times10^{-3}\text{ A}}{e^{0.5800}-1} = 1.177\times10^{-2} = 11.77\text{ mA}.$$

Then can calculate I for $V = 10.0$ mV: $\dfrac{eV}{kT} = \dfrac{(1.602\times10^{-19}\text{ C})(10.0\times10^{-3}\text{ V})}{(1.381\times10^{-23}\text{ J/K})(300\text{ K})} = 0.3867.$

$$I = I_s(e^{eV/kT}-1) = (11.77\text{ mA})(e^{0.3867}-1) = 5.56\text{ mA}.$$

(b) $\dfrac{eV}{kT}$ has the same magnitude as in part (a) but now V is negative so $\dfrac{eV}{kT}$ is negative.

$\underline{V = -15.0\text{ mV}}$: $\dfrac{eV}{kT} = -0.5800$ and $I = I_s(e^{eV/kT}-1) = (11.77\text{ mA})(e^{-0.5800}-1) = -5.18\text{ mA}.$

$\underline{V = -10.0\text{ mV}}$: $\dfrac{eV}{kT} = -0.3867$ and $I = I_s(e^{eV/kT}-1) = (11.77\text{ mA})(e^{-0.3867}-1) = -3.77\text{ mA}.$

EVALUATE: There is a directional asymmetry in the current, with a forward-bias voltage producing more current than a reverse-bias voltage of the same magnitude, but the voltage is small enough for the asymmetry not be pronounced.

42.30. **IDENTIFY:** Apply the equation $I = I_S(e^{eV/kT}-1)$.

SET UP: $I_S = 6.40\text{ mA}$. $\ln e^x = x$.

EXECUTE: **(a)** Solving $I = I_S(e^{eV/kT}-1)$ for the voltage as a function of current gives

$$V = \frac{kT}{e}\ln\left(\frac{I}{I_S}+1\right) = \frac{(1.38\times10^{-23}\text{ J/K})(300\text{ K})}{1.602\times10^{-19}\text{ C}}\ln\left(\frac{40.0\text{ mA}}{6.40\text{ mA}}+1\right) = 0.0512\text{ V} = 51.2\text{ mV}.$$

(b) Using the result from part (a), the quantity $e^{eV/kT} = 7.242$, so for a reverse-bias voltage of the same magnitude, $I = I_S\,(e^{-eV/kT}-1) = (6.40\text{ mA})\left(\dfrac{1}{7.242}-1\right) = -5.52\text{ mA}.$

EVALUATE: The reverse bias current for a given magnitude of voltage is much less than the forward bias current.

42.31. **IDENTIFY:** In this problem we are dealing with a junction diode.

SET UP: We want the resistance of the diode. The current through the junction is given by Eq. (42.22) and $T = 17°\text{C} = 290$ K. Using this equation to find the resistance gives

$$R = \frac{V}{I} = \frac{V}{I_S\left(e^{eV/kT}-1\right)}.$$

EXECUTE: Forward bias: $V = +0.20$ V.

$$R = \frac{0.20\text{ V}}{(10\ \mu\text{A})\left(e^{e(0.20\text{ V})/k(290\text{ K})}-1\right)} = 6.7\ \Omega.$$

Reverse bias: $V = -0.20$ V. Use the same procedure with $V = -0.20$ V, giving $R = 2.0 \times 10^4\ \Omega$.

EVALUATE: In reverse bias the resistance is around 3000 times greater than in forward bias.

42.32. **IDENTIFY** and **SET UP:** $E_l = l(l+1)\dfrac{\hbar^2}{2I}$. ΔE for the molecule is related to λ for the photon by

$$\Delta E = \frac{hc}{\lambda}.$$

EXECUTE: $E_2 = 3\dfrac{\hbar^2}{I}$ and $E_1 = \dfrac{\hbar^2}{I}$, so $\Delta E = \dfrac{2\hbar^2}{I}$. Using $\lambda = 54.3\ \mu$m, we get

$$I = \frac{2\hbar^2}{\Delta E} = \frac{h\lambda}{2\pi^2 c} = 6.08\times10^{-48}\ \text{kg}\cdot\text{m}^2.$$

EVALUATE: The I we calculated is approximately a factor of 24 times smaller than I calculated for the CO molecule in Example 42.2.

42.33. **IDENTIFY** and **SET UP:** From Chapter 21, the electric dipole moment is $p = qd$, where the dipole consists of charges $\pm q$ separated by distance d.

EXECUTE: **(a)** Point charges $+e$ and $-e$ separated by distance d, so

$$p = ed = (1.602\times10^{-19}\ \text{C})(0.24\times10^{-9}\ \text{m}) = 3.8\times10^{-29}\ \text{C}\cdot\text{m}.$$

(b) $p = qd$, so $q = \dfrac{p}{d} = \dfrac{3.0\times10^{-29}\ \text{C}\cdot\text{m}}{0.24\times10^{-9}\ \text{m}} = 1.3\times10^{-19}\ \text{C}.$

(c) $\dfrac{q}{e} = \dfrac{1.3\times10^{-19}\ \text{C}}{1.602\times10^{-19}\ \text{C}} = 0.81.$

(d) $q = \dfrac{p}{d} = \dfrac{1.5\times10^{-30}\ \text{C}\cdot\text{m}}{0.16\times10^{-9}\ \text{m}} = 9.37\times10^{-21}\ \text{C}.$

$$\frac{q}{e} = \frac{9.37\times10^{-21}\ \text{C}}{1.602\times10^{-19}\ \text{C}} = 0.058.$$

EVALUATE: The fractional ionic character for the bond in HI is much less than the fractional ionic character for the bond in NaCl. The bond in HI is mostly covalent and not very ionic.

42.34. **IDENTIFY** and **SET UP:** For an $l \to l-1$ transition, the frequency of the emitted photon is

$$f = \frac{\Delta E}{h} = \frac{\Delta E}{2\pi\hbar} = \frac{l\hbar}{2\pi I},\ \text{so}\ \Delta E = \frac{l\hbar^2}{I}.$$

$$I = m_\text{r} r_0^2.\ m_\text{r} = \frac{(3.82\times10^{-26}\text{kg})(3.15\times10^{-26}\ \text{kg})}{3.82\times10^{-26}\ \text{kg} + 3.15\times10^{-26}\ \text{kg}} = 1.726\times10^{-26}\ \text{kg}.$$

EXECUTE: $I = \dfrac{\hbar^2 l}{\Delta E} = \dfrac{hl\lambda}{4\pi^2 c} = 6.43\times10^{-46}\ \text{kg}\cdot\text{m}^2$ and from $I = m_\text{r} r_0^2$ the separation is

$$r_0 = \sqrt{\frac{I}{m_\text{r}}} = 0.193\ \text{nm}.$$

EVALUATE: Section 42.1 says $r_0 = 0.24$ nm for NaCl. Our result for NaF is smaller than this. This makes sense, since F is a smaller atom than Cl.

42.35. **IDENTIFY:** $E_\text{ex} = \dfrac{L^2}{2I} = \dfrac{\hbar^2 l(l+1)}{2I}$. $E_g = 0\ (l = 0)$, and there is an additional multiplicative factor of $2l+1$ because for each l state there are really $(2l+1)$ m_l states with the same energy.

SET UP: From Example 42.2, $I = 1.449\times10^{-46}\ \text{kg}\cdot\text{m}^2$ for CO.

EXECUTE: **(a)** $\dfrac{n_l}{n_0} = (2l+1)e^{-\hbar^2 l(l+1)/(2IkT)}.$

(b) (i) $E_{l=1} = \dfrac{\hbar^2(1)(1+1)}{2(1.449\times10^{-46}\ \text{kg}\cdot\text{m}^2)} = 7.67\times10^{-23}\ \text{J}.$ $\dfrac{E_{l=1}}{kT} = \dfrac{7.67\times10^{-23}\ \text{J}}{(1.38\times10^{-23}\ \text{J/K})(300\ \text{K})} = 0.0185.$

$$(2l+1) = 3,\ \text{so}\ \frac{n_{l=1}}{n_0} = (3)e^{-0.0185} = 2.95.$$

(ii) $\dfrac{E_{l=2}}{kT} = \dfrac{\hbar^2(2)\,(2+1)}{2(1.449\times10^{-46}\ \text{kg}\cdot\text{m}^2)(1.38\times10^{-23}\ \text{J/K})(300\ \text{K})} = 0.0556.$ $(2l+1) = 5,$ so

$$\frac{n_{l=1}}{n_0} = (5)(e^{-0.0556}) = 4.73.$$

(iii) $\dfrac{E_{l=10}}{kT} = \dfrac{\hbar^2(10)\,(10+1)}{2(1.449\times10^{-46}\ \text{kg}\cdot\text{m}^2)(1.38\times10^{-23}\ \text{J/K})(300\ \text{K})} = 1.02.$

$$(2l+1) = 21,\ \text{so}\ \frac{n_{l=10}}{n_0} = (21)(e^{-1.02}) = 7.57.$$

(iv) $\dfrac{E_{l=20}}{kT} = \dfrac{\hbar^2(20)(20+1)}{2(1.449\times10^{-46}\ \text{kg}\cdot\text{m}^2)\,(1.38\times10^{-23}\ \text{J/K})\,(300\ \text{K})} = 3.90.$ $(2l+1) = 41,$ so

$$\frac{n_{l=20}}{n_0} = (41)e^{-3.90} = 0.833.$$

(v) $\dfrac{E_{l=50}}{kT} = \dfrac{\hbar^2(50)(50+1)}{2(1.449\times10^{-46}\ \text{kg}\cdot\text{m}^2)(1.38\times10^{-23}\ \text{J/K})(300\ \text{K})} = 23.7.$ $(2l+1) = 101,$ so

$$\frac{n_{l=50}}{n_0} = (101)e^{-23.7} = 5.38\times10^{-9}.$$

EVALUATE: **(c)** There is a competing effect between the $(2l+1)$ term and the decaying exponential. The $2l+1$ term dominates for small l, while the exponential term dominates for large l.

42.36. **IDENTIFY:** The ratio n_l/n_0 will be largest when its derivative with respect to l is zero.

SET UP: From Problem 42.35, we know that $n_l/n_0 = (2l+1)e^{-\hbar^2 l(l+1)/2IkT}$. Set $\dfrac{\partial(n_l/n_0)}{\partial l} = 0$ and solve for l.

EXECUTE: **(a)** $\dfrac{\partial}{\partial l}\left[(2l+1)e^{-\hbar^2 l(l+1)/2IkT}\right] = 2e^{-\hbar^2 l(l+1)/2IkT} - \dfrac{(2l+1)^2\hbar^2}{2IkT}e^{-\hbar^2 l(l+1)/2IkT} = 0.$

The exponentials cannot be zero, so

$$2 - \frac{(2l+1)^2\hbar^2}{2IkT} = 0 \ \rightarrow\ l_{\text{max}} = \frac{\sqrt{IkT}}{\hbar} - \frac{1}{2}.$$

(b) Using $I = 1.449\times10^{-46}\ \text{kg}\cdot\text{m}^2$ for CO from Example 42.2 gives

$$l_{\text{max}} = \frac{\sqrt{(1.449\times10^{-46}\ \text{kg}\cdot\text{m}^2)(1.38\times10^{-23}\ \text{J/K})(300\ \text{K})}}{1.055\times10^{-34}\ \text{J}\cdot\text{s}} - \frac{1}{2} = 6.84 \approx 7.$$

EVALUATE: Since $l_{\text{max}} \propto \sqrt{I}$, it would have a different value for molecules other than CO.

42.37. **IDENTIFY:** This problem is about the power in a diode.
SET UP: We use Eq. (42.22) and $P = IV$.
EXECUTE: **(a)** We want the power.

$$P = IV = I_{\text{S}}\left(e^{eV/kT} - 1\right)V = (1.2\times10^{-11}\ \text{A})\left(e^{e(0.6\ \text{V})/k(300\ \text{K})} - 1\right)(0.6V) = 85\ \text{mW}.$$

(b) We want V when $P = 500$ mA $= 0.5$ A. We can solve this by trial-and-error. First put the equation in the convenient form

$$P = (1.2\times10^{-11}\text{ A})\left(e^{(38.65\text{ V}^{-1})V} - 1\right)V$$

We know that V must be greater than 0.6 V. Trying $V = 0.8$ V gives $P = 260$ W. Trying $V = 0.7$ V gives $P = 4.7$ W. Trying $V = 0.65$ V gives $P = 635$ mW. Trying $V = 0.64$ V gives $P = 425$ mW. Trying $V = 0.645$ V gives $P = 520$ mW, which is close enough to 500 mA. So the maximum voltage is $V = 0.645$ V. To one significant figure, the answer is $V = 0.6$ V.

(c) We want the current when $V = 0.645$ V. $I = P/V = (520\text{ mW})/(0.645\text{ V}) = 0.81$ A.

EVALUATE: Note in part (b) how sensitive the power is to small changes in V due to the exponential.

42.38. **IDENTIFY:** The rotational energy levels are given by $E_l = l(l+1)\dfrac{\hbar^2}{2I}$. The transition energy ΔE for the molecule and λ for the photon are related by $\Delta E = \dfrac{hc}{\lambda}$.

SET UP: From Example 42.2, $I_{\text{CO}} = 1.449\times10^{-46}\text{ kg}\cdot\text{m}^2$.

EXECUTE: **(a)** $E_{l=1} = \dfrac{\hbar^2 l(l+1)}{2I} = \dfrac{(1.054\times10^{-34}\text{ J}\cdot\text{s})^2(1)(1+1)}{2(1.449\times10^{-46}\text{ kg}\cdot\text{m}^2)} = 7.67\times10^{-23}\text{ J}$. $E_{l=0} = 0$.

$\Delta E = 7.67\times10^{-23}\text{ J} = 4.79\times10^{-4}\text{ eV}$. $\lambda = \dfrac{hc}{\Delta E} = \dfrac{(6.63\times10^{-34}\text{ J}\cdot\text{s})(3.00\times10^{8}\text{ m/s})}{(7.67\times10^{-23}\text{ J})}$

$= 2.59\times10^{-3}\text{ m} = 2.59\text{ mm}$.

EVALUATE: **(b)** Let's compare the value of kT when $T = 20K$ to that of ΔE for the $l = 1 \to l = 0$ rotational transition: $kT = (1.38\times10^{-23}\text{ J/K})(20\text{ K}) = 2.76\times10^{-22}\text{ J}$.

$\Delta E = 7.67\times10^{-23}$ J (from part (a)). So $\dfrac{kT}{\Delta E} = 3.60$. Therefore, although T is quite small, there is still plenty of energy to excite CO molecules into the first rotational level. This allows astronomers to detect the 2.59 mm wavelength radiation from such molecular clouds.

42.39. **IDENTIFY:** The vibrational energy levels are given by $E_n = (n+\frac{1}{2})\,\hbar\sqrt{\dfrac{k'}{m_\text{r}}}$. The zero-point energy is

$$E_0 = \tfrac{1}{2}\hbar\sqrt{\frac{2k'}{m_\text{H}}}.$$

SET UP: For H_2, $m_\text{r} = \dfrac{m_\text{H}}{2}$.

EXECUTE: $E_0 = \frac{1}{2}(1.054\times10^{-34}\text{ J}\cdot\text{s})\sqrt{\dfrac{2(576\text{ N/m})}{1.67\times10^{-27}\text{ kg}}} = 4.38\times10^{-20}\text{ J} = 0.274\text{ eV}$.

EVALUATE: This is much less than the magnitude of the H_2 bond energy.

42.40. **IDENTIFY:** $\Delta E = hf = \hbar\sqrt{\dfrac{k'}{m_\text{r}}}$.

SET UP: $m_\text{r} = \dfrac{m_\text{O}m_\text{H}}{m_\text{O}+m_\text{H}} = 1.57\times10^{-27}$ kg.

EXECUTE: The vibration frequency is $f = \dfrac{\Delta E}{h} = 1.12\times10^{14}$ Hz. The force constant is

$$k' = (2\pi f)^2 m_\text{r} = 777\text{ N/m}.$$

EVALUATE: This would be a fairly stiff spring in an ordinary physics lab.

42.41. **IDENTIFY** and **SET UP:** Use $I = m_r r_0^2$ to calculate I. The energy levels are given by $E_{nl} = l(l+1)\left(\frac{\hbar^2}{2I}\right) + (n+\frac{1}{2})\hbar\sqrt{\frac{k'}{m_r}}$. The transition energy ΔE is related to the photon wavelength by $\Delta E = hc/\lambda$.

EXECUTE: **(a)** $m_r = \frac{m_H m_I}{m_H + m_I} = \frac{(1.67\times10^{-27}\text{ kg})(2.11\times10^{-25}\text{ kg})}{1.67\times10^{-27}\text{ kg} + 2.11\times10^{-25}\text{ kg}} = 1.657\times10^{-27}\text{ kg}$.

$$I = m_r r_0^2 = (1.657\times10^{-27}\text{ kg})(0.160\times10^{-9}\text{ m})^2 = 4.24\times10^{-47}\text{ kg}\cdot\text{m}^2.$$

(b) The energy levels are $E_{nl} = l(l+1)\left(\frac{\hbar^2}{2I}\right) + (n+\frac{1}{2})\hbar\sqrt{\frac{k'}{m_r}}$.

$$\sqrt{\frac{k'}{m}} = \omega = 2\pi f, \text{ so } E_{nl} = l(l+1)\left(\frac{\hbar^2}{2I}\right) + (n+\tfrac{1}{2})hf.$$

(i) Transition $n = 1 \to n = 0, l = 1 \to l = 0$:

$$\Delta E = (2-0)\left(\frac{\hbar^2}{2I}\right) + (1+\tfrac{1}{2}-\tfrac{1}{2})hf = \frac{\hbar^2}{I} + hf.$$

$$\Delta E = \frac{hc}{\lambda}, \text{ so } \lambda = \frac{hc}{\Delta E} = \frac{hc}{(\hbar^2/I) + hf} = \frac{c}{(\hbar/2\pi I) + f}.$$

$$\frac{\hbar}{2\pi I} = \frac{1.055\times10^{-34}\text{ J}\cdot\text{s}}{2\pi(4.24\times10^{-47}\text{ kg}\cdot\text{m}^2)} = 3.960\times10^{11}\text{ Hz}.$$

$$\lambda = \frac{c}{(\hbar/2\pi I) + f} = \frac{2.998\times10^8\text{ m/s}}{3.960\times10^{11}\text{ Hz} + 6.93\times10^{13}\text{ Hz}} = 4.30\ \mu\text{m}.$$

(ii) Transition $n = 1 \to n = 0, l = 2 \to l = 1$:

$$\Delta E = (6-2)\left(\frac{\hbar^2}{2I}\right) + hf = \frac{2\hbar^2}{I} + hf.$$

$$\lambda = \frac{c}{2(\hbar/2\pi I) + f} = \frac{2.998\times10^8\text{ m/s}}{2(3.960\times10^{11}\text{ Hz}) + 6.93\times10^{13}\text{ Hz}} = 4.28\ \mu\text{m}.$$

(iii) Transition $n = 2 \to n = 1, l = 2 \to l = 3$:

$$\Delta E = (6-12)\left(\frac{\hbar^2}{2I}\right) + hf = -\frac{3\hbar^2}{I} + hf.$$

$$\lambda = \frac{c}{-3(\hbar/2\pi I) + f} = \frac{2.998\times10^8\text{ m/s}}{-3(3.960\times10^{11}\text{ Hz}) + 6.93\times10^{13}\text{ Hz}} = 4.40\ \mu\text{m}.$$

EVALUATE: The vibrational energy change for the $n = 1 \to n = 0$ transition is the same as for the $n = 2 \to n = 1$ transition. The rotational energies are much smaller than the vibrational energies, so the wavelengths for all three transitions don't differ much.

42.42. **IDENTIFY:** The frequency is proportional to the reciprocal of the square root of the reduced mass. The transition energy ΔE and the wavelength of the light emitted are related by $\Delta E = \frac{hc}{\lambda}$.

SET UP: $f_0 = 1.24\times10^{14}$ Hz.

EXECUTE: **(a)** In terms of the atomic masses, the frequency of the isotope with the deuterium atom is $f = f_0\left(\frac{m_F m_H/(m_H + m_F)}{m_F m_D/(m_D + m_F)}\right)^{1/2} = f_0\left(\frac{1+(m_F/m_D)}{1+(m_F/m_H)}\right)^{1/2}$. Using f_0 and the given masses, $f = 8.99\times10^{13}$ Hz.

(b) For the molecule, $\Delta E = hf$. $hf = \dfrac{hc}{\lambda}$, so $\lambda = \dfrac{c}{f} = \dfrac{3.00\times10^{8}\ \text{m/s}}{8.99\times10^{13}\ \text{Hz}} = 3.34\times10^{-6}\ \text{m} = 3340\ \text{nm}$. This wavelength is in the infrared.

EVALUATE: The vibrational frequency of the molecule equals the frequency of the light that is emitted.

42.43. **IDENTIFY:** E_{F0} is given by $E_{\text{F0}} = \dfrac{3^{2/3}\pi^{4/3}\hbar^2 n^{2/3}}{2m}$. Since potassium is a metal and E does not change much with T for metals, we approximate E_{F} by E_{F0}, so $E_{\text{F}} = \dfrac{3^{2/3}\pi^{4/3}\hbar^2 n^{2/3}}{2m}$.

SET UP: The number of atoms per m^3 is ρ/m. If each atom contributes one free electron, the electron concentration is $n = \dfrac{\rho}{m} = \dfrac{851\ \text{kg/m}^3}{6.49\times10^{-26}\ \text{kg}} = 1.31\times10^{28}\ \text{electrons/m}^3$.

EXECUTE: $E_{\text{F}} = \dfrac{3^{2/3}\pi^{4/3}(1.054\times10^{-34}\ \text{J}\cdot\text{s})^2(1.31\times10^{28}/\text{m}^3)^{2/3}}{2(9.11\times10^{-31}\ \text{kg})} = 3.24\times10^{-19}\ \text{J} = 2.03\ \text{eV}$.

EVALUATE: The E_{F} we calculated for potassium is about a factor of three smaller than the E_{F} for copper that was calculated in Example 42.7.

42.44. **IDENTIFY** and **SET UP:** At r where U_{tot} is a minimum, $\dfrac{d}{dr}U_{\text{tot}} = 0$.

EXECUTE: **(a)** $\dfrac{d}{dr}U_{\text{tot}} = \dfrac{\alpha e^2}{4\pi\epsilon_0}\dfrac{1}{r^2} - 8A\dfrac{1}{r^9}$. Setting this equal to zero when $r = r_0$ gives $r_0^7 = \dfrac{8A4\pi\epsilon_0}{\alpha e^2}$ and so $U_{\text{tot}} = \dfrac{\alpha e^2}{4\pi\epsilon_0}\left(-\dfrac{1}{r} + \dfrac{r_0^7}{8r^8}\right)$. At $r = r_0$, $U_{\text{tot}} = -\dfrac{7\alpha e^2}{32\pi\epsilon_0 r_0} = -1.26\times10^{-18}\ \text{J} = -7.85\ \text{eV}$.

(b) To remove a Na^+Cl^- ion pair from the crystal requires 7.85 eV. When neutral Na and Cl atoms are formed from the Na^+ and Cl^- atoms there is a net release of energy $-5.14\ \text{eV} + 3.61\ \text{eV} = -1.53\ \text{eV}$, so the net energy required to remove a neutral Na Cl pair from the crystal is

$$7.85\ \text{eV} - 1.53\ \text{eV} = 6.32\ \text{eV}.$$

EVALUATE: Our calculation is in good agreement with the experimental value.

42.45. **IDENTIFY** and **SET UP:** Use the description of the bcc lattice in Figure 42.11c in the textbook to calculate the number of atoms per unit cell and then the number of atoms per unit volume.

EXECUTE: **(a)** Each unit cell has one atom at its center and 8 atoms at its corners that are each shared by 8 other unit cells. So there are $1 + 8/8 = 2$ atoms per unit cell.

$$\frac{n}{V} = \frac{2}{(0.35\times10^{-9}\text{m})^3} = 4.66\times10^{-8}\ \text{atoms/m}^3.$$

(b) $E_{\text{F0}} = \dfrac{3^{2/3}\pi^{4/3}\hbar^2}{2m}\left(\dfrac{N}{V}\right)^{2/3}$.

In this equation *N/V* is the number of free electrons per m^3. But the problem says to assume one free electron per atom, so this is the same as *n/V* calculated in part (a).

$m = 9.109\times10^{-31}\ \text{kg}$ (the electron mass), so $E_{\text{F0}} = 7.563\times10^{-19}\ \text{J} = 4.7\ \text{eV}$.

EVALUATE: Our result for metallic lithium is similar to that calculated for copper in Example 42.7.

42.46. **(a) IDENTIFY:** The rotational energy levels are given by $E_l = l(l+1)\dfrac{\hbar^2}{2I}$. The photon wavelength λ is related to the transition energy of the atom by $\Delta E = \dfrac{hc}{\lambda}$.

SET UP: For emission, $\Delta l = -1$. For such a transition, from state l to state $l-1$, we have $\Delta E_l = [l(l+1)-(l-1)l]\dfrac{\hbar^2}{2I} = \dfrac{l\hbar^2}{I}$. The difference in transition energies for adjacent lines in the spectrum is $\Delta E = \Delta E_l - \Delta E_{l-1} = \dfrac{\hbar^2}{I}$.

EXECUTE: The transition energies corresponding to the observed wavelengths are 3.29×10^{-21} J, 2.87×10^{-21} J, 2.47×10^{-21} J, 2.06×10^{-21} J, and 1.65×10^{-21} J. The average spacing of these energies is 0.410×10^{-21} J. Then, $\dfrac{\hbar^2}{I} = 0.410\times10^{-21}$ J, from which $I = 2.71\times10^{-47}\ \text{kg}\cdot\text{m}^2$.

EVALUATE: With $\dfrac{\hbar^2}{I} = 0.410\times10^{-21}$ J and $\Delta E_l = \dfrac{l\hbar^2}{I}$, we find that these wavelengths correspond to transitions from levels 8, 7, 6, 5, and 4 to the respective next lower levels.

(b) IDENTIFY: Each transition is from the level l to the level $l-1$. The rotational energies are given by $E_l = l(l+1)\dfrac{\hbar^2}{2I}$. The transition energy is related to the photon wavelength by $\Delta E = hc/\lambda$.

SET UP: $E_l = l(l+1)\hbar^2/2I$, so $\Delta E = E_l - E_{l-1} = [l(l+1) - l(l-1)]\left(\dfrac{\hbar^2}{2I}\right) = l\left(\dfrac{\hbar^2}{I}\right)$.

EXECUTE: $l\left(\dfrac{\hbar^2}{I}\right) = \dfrac{\hbar c}{\lambda}$.

$$l = \frac{2\pi c I}{\hbar\lambda} = \frac{2\pi(2.998\times10^8\ \text{m/s})(2.71\times10^{-47}\ \text{kg}\cdot\text{m}^2)}{(1.055\times10^{-34}\ \text{J}\cdot\text{s})\lambda} = \frac{4.843\times10^{-4}\ \text{m}}{\lambda}.$$

For $\lambda = 60.4\ \mu\text{m}$, $l = \dfrac{4.843\times10^{-4}\ \text{m}}{60.4\times10^{-6}\ \text{m}} = 8.$

For $\lambda = 69.0\ \mu\text{m}$, $l = \dfrac{4.843\times10^{-4}\ \text{m}}{69.0\times10^{-6}\ \text{m}} = 7.$

For $\lambda = 80.4\ \mu\text{m}$, $l = \dfrac{4.843\times10^{-4}\ \text{m}}{80.4\times10^{-6}\ \text{m}} = 6.$

For $\lambda = 96.4\ \mu\text{m}$, $l = \dfrac{4.843\times10^{-4}\ \text{m}}{96.4\times10^{-6}\ \text{m}} = 5.$

For $\lambda = 120.4\ \mu\text{m}$, $l = \dfrac{4.843\times10^{-4}\ \text{m}}{120.4\times10^{-6}\ \text{m}} = 4.$

EVALUATE: In each case l is an integer, as it must be.

(c) IDENTIFY: The rotational energies of a molecule depend on its moment of inertia, which in turn depends on the separation between the atoms in the molecule.

SET UP: Part (a) gives $I = 2.71\times10^{-47}\ \text{kg}\cdot\text{m}^2$. $I = m_r r^2$. Calculate m_r and solve for r.

EXECUTE: $m_r = \dfrac{m_H m_{Cl}}{m_H + m_{Cl}} = \dfrac{(1.67\times10^{-27}\ \text{kg})(5.81\times10^{-26}\ \text{kg})}{1.67\times10^{-27}\ \text{kg} + 5.81\times10^{-26}\ \text{kg}} = 1.623\times10^{-27}\ \text{kg}.$

$$r = \sqrt{\frac{I}{m_r}} = \sqrt{\frac{2.71\times10^{-47}\ \text{kg}\cdot\text{m}^2}{1.623\times10^{-27}\ \text{kg}}} = 1.29\times10^{-10}\ \text{m} = 0.129\ \text{nm}.$$

EVALUATE: This is a typical atomic separation for a diatomic molecule; see Example 42.2 for the corresponding distance for CO.

(d) IDENTIFY and SET UP: The longest λ implies the smallest ΔE, and this is for the transition from $l = 1$ to $l = 0$.

EXECUTE: $\Delta E = l\left(\dfrac{\hbar^2}{I}\right) = (1)\dfrac{(1.055\times10^{-34}\ \text{J}\cdot\text{s})^2}{2.71\times10^{-47}\ \text{kg}\cdot\text{m}^2} = 4.099\times10^{-22}\ \text{J}.$

$\lambda = \dfrac{hc}{\Delta E} = \dfrac{(6.626\times10^{-34}\ \text{J}\cdot\text{s})(2.998\times10^{8}\ \text{m/s})}{4.099\times10^{-22}\ \text{J}} = 4.85\times10^{-4}\ \text{m} = 485\ \mu\text{m}.$

EVALUATE: This is longer than any wavelengths in part (b).

42.47. **IDENTIFY** and **SET UP:** The occupation probability $f(E)$ is $f(E) = \dfrac{1}{e^{(E-E_{\text{F}})/kT}+1}$.

EXECUTE: **(a)** Figure 42.47 shows the graph of E versus $\ln\{[1/f(E)]-1\}$ for the data given in the problem. The slope of the best-fit straight line is 0.445 eV, and the y-intercept is 1.80 eV.

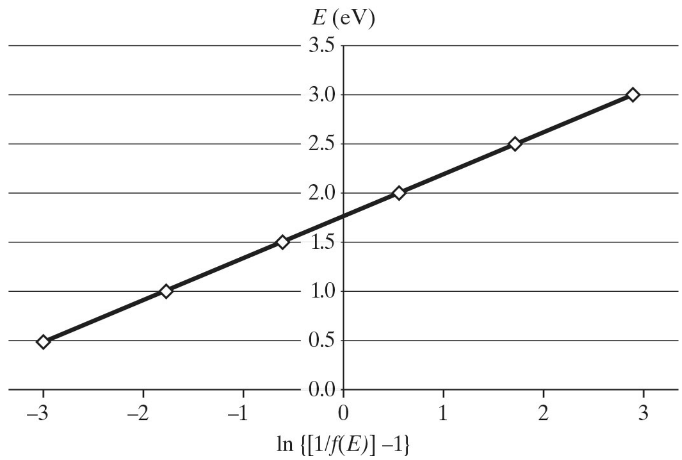

Figure 42.47

(b) Solve the $f(E)$ equation for E, giving $e^{(E-E_{\text{F}})/kT} = 1/f(E)-1$. Now take natural logarithms of both side of the equation, giving $(E-E_{\text{F}})/kT = \ln\{[1/f(E)]-1\}$, which gives $E = kT\ln\{[1/f(E)]-1\}+E_{\text{F}}$. From this we see that a graph of E versus $\ln\{[1/f(E)]-1\}$ should be a straight line having a slope equal to kT and a y-intercept equal to E_{F}. From our graph, we get E_{F} = y-intercept = 1.80 eV.

The slope is equal to kT, so $T = (\text{slope})/k = (0.445\ \text{eV})/(1.38\times10^{-23}\ \text{J/K})$

$= (7.129\times10^{-20}\ \text{J})/(1.38\times10^{-23}\ \text{J/K})$

$= 5170\ \text{K}.$

EVALUATE: In Example 42.7, the Fermi energy for copper was found to be 7.03 eV, so our result of 1.80 eV seems plausible.

42.48. **IDENTIFY** and **SET UP:** We assume that the equation $I = I_{\text{S}}(e^{eV/kT}-1)$ applies for this p-n junction. Use the given information for I and V to calculate the saturation current I_{S} and the temperature T for the junction.

EXECUTE: Put the numbers given in the problem into the equation for the current.

$0.407\ \text{mA} = I_{\text{S}}(e^{(1.60\times10^{-19}\ \text{C})(0.00500\ \text{V})/(1.38\times10^{-23}\ \text{J/K})T}-1) = I_{\text{S}}(e^{(57.97\ \text{K})/T})-1.$

$-0.338\ \text{mA} = I_{\text{S}}(e^{(1.60\times10^{-19}\ \text{C})(-0.00500\ \text{V})/(1.38\times10^{-23}\ \text{J/K})T}-1) = I_{\text{S}}(e^{(-57.97\ \text{K})/T})-1.$

Dividing the two equations gives $\dfrac{0.407}{0.338} = \dfrac{(e^{(57.97\ \text{K})/T})-1}{(e^{(-57.97\ \text{K})/T})-1}$.

Cross-multiplying and simplifying gives $e^{(57.97\ \text{K})/T} - 2.204 + 1.204e^{-(57.97\ \text{K})/T} = 0$.

Letting $x = e^{(57.97\ \text{K})/T}$, this equation becomes $x - 2.204 + 1.204x^{-1} = 0$.

Multiplying by x gives the quadratic equation $x^2 - 2.204x + 1.204 = 0$.
The two solutions are $x = 1.00$ or $x = 1.204$. The $x = 1.00$ solution would require $T = \infty$, which is not physically possible, so $x = 1.204$ is the solution to use. This gives $1.204 = e^{(57.97\text{ K})/T}$. Taking natural logarithms of both sides gives $\ln(1.204) = (57.97\text{ K})/T$, so $T = (57.97\text{ K})/\ln(1.204) = 312\text{ K}$.

The saturation current is $I_S = \dfrac{I}{e^{eV/kT} - 1} = \dfrac{0.407\text{ mA}}{e^{(1.60\times10^{-19}\text{ C})(0.00500\text{ V})/[(1.38\times10^{-23}\text{ J/K})(312\text{ K})]} - 1} = 1.99\text{ mA}$.

EVALUATE: 312 K = 39°C = 102°F, which is quite a bit warmer than room temperature (≈20°C). A current of about 2 mA is not unusual in laboratory apparatus.

42.49. **IDENTIFY:** This problem involves a semiconductor device used to make a half-wave rectifier.
SET UP: Eq. (42.22) gives the current through the junction of the semiconductor. The saturation current is 5×10^{-13} A and $T = 300$ K.
EXECUTE: **(a)** We want the minimum V_{out}, so $I = 1\ \mu$A. Solve Eq. (42.22) for V. (Careful! In this equation, e is the charge of an electron, not the base for natural logarithms.)

$$V_{out} = \frac{kT}{e}\ln\left(1+\frac{I}{I_S}\right) = \frac{k(300\text{ K})}{e}\ln\left(1+\frac{1\,\mu\text{A}}{5\times10^{-13}\text{ A}}\right) = 0.375\text{ V}.$$

(b) We want the maximum V_{out}. Combine Eq. (42.22) and $I = V/R_D$ and solve for V. Note that $e/kT = e/[k(300\text{ K})] = 38.65\text{ V}^{-1}$.

$$V = R_D I = R_D I_S\left(e^{eV/kT} - 1\right) = (100\ \Omega)(5\times10^{-13}\text{ A})\left(e^{(38.65\text{ V}^{-1})V} - 1\right).$$

Solve this equation by trial-and-error or using mathematical software. The result is $V_{max} = 0.6$ V.
(c) We want the current. $I = V/R_D = (0.6\text{ V})/(100\ \Omega) = 0.006$ A.
(d) If $V_{in} > V_{max}$: $V_{out} = V_{max} = 0.6$ V.
If $V_{in} < V_{max}$: $V_{out} = V_{in}$.
EVALUATE: The exponential behavior makes I very sensitive to changes in V.

49.50. **IDENTIFY:** We are dealing with a p-n junction diode.

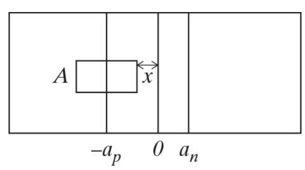

Figure 42.50

SET UP and **EXECUTE:** **(a)** We want the electric field on the p side of the junction. Apply Gauss's law using the Gaussian surface shown in Figure 42.50 and follow the hint in the problem.

$\int KE\cos\theta\, dA = Q/\epsilon_0$, where $Q - eN_A(x - a_p)$.

$$KEA\cos\pi = \frac{-eN_A(a_p - x)A}{\epsilon_0}$$

$$E_x = -\frac{eN_A(x - a_p)}{K\epsilon_0}.$$

(b) We want the electric field on the n side of the junction. Use the same procedure as in part (a) except that the Gaussian surface lies to the right of $x = 0$ and extends into the n region. The result is

$$KEA\cos 0° = \frac{-eN_D(a_n - x)A}{\epsilon_0}$$

$$E_x = -\frac{eN_D(a_n - x)}{K\epsilon_0}.$$

(c) By continuity, at $x = 0$ the field must be the same for both expressions.

$$-\frac{eN_\mathrm{A}(x-a_p)}{K\epsilon_0} = -\frac{eN_\mathrm{D}(a_n-x)}{K\epsilon_0} \rightarrow N_\mathrm{A}a_p = N_\mathrm{D}a_n.$$

(d) We want $V(x)$. Use Eq. (23.18) as advised in the problem.

$$V(x)-V_0 = -\int E_x\,dx = -\int_{-a_p}^{-x} -\frac{eN_\mathrm{A}}{K\epsilon_0}(x'-a_p)dx' = \frac{eN_\mathrm{A}}{K\epsilon_0}\left(\frac{x^2}{2}+a_p x+\frac{3}{2}a_p^2\right).$$

Now use the requirement that $V(x) = 0$ when $x = -a_p$ to find V_0.

$$-V_0 = \frac{eN_\mathrm{A}}{K\epsilon_0}\left(\frac{a_p^2}{2}-a_p^2+\frac{3}{2}a_p^2\right) = \frac{eN_\mathrm{A}}{K\epsilon_0}a_p^2.$$

Putting this result into our equation for $V(x)$ and combining terms gives

$$V(x) = \frac{eN_\mathrm{A}}{2K\epsilon_0}(x+a_p)^2.$$

(e) We want $V(x)$ on the other side of the junction. Using the same approach as in part (d) gives

$$V(x)-V_0 - \int E_x\,dx = -\int_0^x -\frac{eN_\mathrm{D}}{K\epsilon_0}(a_n-x')\,dx' = \frac{eN_\mathrm{D}}{K\epsilon_0}\left(a_n x-\frac{x^2}{2}\right).$$

From part (d) we know $V(0)$ at $x = 0$. From our result above we know that $V(0) = V_0$. So

$$V_0 = \frac{eN_\mathrm{A}}{2K\epsilon_0}a_p^2.$$

Using this in our result for $V(x)$ gives

$$V(x) = \frac{eN_\mathrm{A}a_p^2}{2K\epsilon_0} - \frac{eN_\mathrm{D}}{2K\epsilon_0}\left(x^2-2a_n x\right).$$

(f) We want the potential barrier $V_b = V(a_n) - V(-a_p)$. $V_b = V(a_n)$ because $V(-a_p) = 0$. Using the result from part (e) gives

$$V_b = \frac{eN_\mathrm{A}a_p^2}{2K\epsilon_0} - \frac{eN_\mathrm{D}}{2K\epsilon_0}\left(a_n^2-2a_n^2\right) = \frac{e}{2K\epsilon_0}\left(N_\mathrm{A}a_p^2+N_\mathrm{D}a_n^2\right).$$

(g) We want a_p. Using the results from part (c) and the values for the variables given in the problem, we have

$$a_p = a_n\frac{N_\mathrm{D}}{N_\mathrm{A}} = 275\ \text{nm}.$$

(h) We want the peak electric field at $x = 0$. We can use either equation for E because of continuity and evaluate it at $x = 0$ with $K = 11.7$, giving

$$E = \frac{eN_\mathrm{D}a_n}{K\epsilon_0} = 4.25\ \text{MV/m}.$$

(i) We want V_b. Use the results from part (f) and the given values and result from part (g). This gives

$$V_\mathrm{b} = \frac{e}{2K\epsilon_0}\left(N_\mathrm{A}a_p^2+N_\mathrm{D}a_n^2\right) = 0.701\ \text{V}.$$

EVALUATE: The electric field in part (h) is quite small compared to many lab fields.

42.51. IDENTIFY: We are looking at the vibrations of the CO_2 molecule.

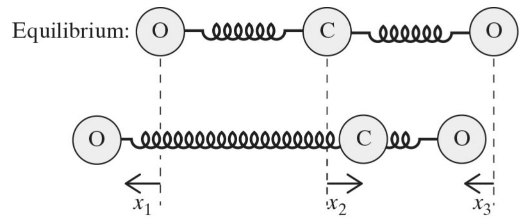

Figure 42.51

SET UP: According to the textbook description with Figure 42.10(c) for the asymmetric stretching mode, when carbon moves to the right, oxygen atoms move to the left, and when carbon moves to the left, they move to the right. Figure 42.51 shows the atoms in both their equilibrium configuration and displaced as described. First use Hooke's law to find the net force on each atom and then apply Newton's second law. Follow the instructions for each part of the problem.

EXECUTE: **(a)** Force on the left oxygen atom: This force is to the right. $F_{O1} = k'(x_2 + |x_1|)$. But x_1 is negative, so $|x_1| = -x_1$. Therefore, $F_{O1} = k'(x_2 - x_1) = -k'(x_1 - x_2)$.

Force on the carbon atom: The force due to the left-hand oxygen atom is to the left and the force due to the right-hand oxygen atom is also to the left. The net force is the sum of these two.

$F_C = -k'(x_2 + |x_1|) - k'(x_2 + |x_3|) = -k'(x_2 - x_1) - k'(x_2 - x_3) = k'(x_1 - 2x_2 + x_3)$.

Force on the right oxygen atom: This force is to the right.

$$F_{O2} = k'(x_2 + |x_3|) = k'(x_2 - x_3).$$

The corresponding equations for Newton's second law are

$$M_O\ddot{x}_1 = -k'(x_1 - x_2)$$

$$M_C\ddot{x}_2 = -k'(x_1 - 2x + x_3)$$

$$M_O\ddot{x}_3 = -k'(x_2 - x_3).$$

(b) Making the substitutions suggested in the problem, the Newton's second law equation become

$$M_O\ddot{X}_O = -k'(X_O + X_C)$$

$$-M_C\ddot{X}_C = k'(X_O + 2X_C + X_O) = 2k'(X_O + X_C)$$

$$M_O\ddot{X}_O = k'(-X_C - X_O) = -k'(X_C + X_O)$$

Combining these three equations, we find that the two independent equations are

$$M_O\ddot{X}_O = -k'(X_O + X_C)$$

$$M_C\ddot{X}_C = -2k'(X_O + X_C).$$

(c) Eliminating $X_C + X_O$ gives

$$M_C\ddot{X}_C = 2M_O\ddot{X}_O$$

Now solve this differential equation.

$$M_C\frac{d\dot{X}_C}{dt} = 2M_O\frac{d\dot{X}_O}{dt}$$

$$\dot{X}_C = \frac{2M_O}{M_C}\dot{X}_O$$

$$X_C = \frac{2M_O}{M_C}X_O.$$

(d) Following the directions gives

$$M_O\ddot{X}_O = -k'(X_O + X_C) = -k'\left(\frac{2M_O}{M_C}X_O + X_O\right)$$

$$\frac{M_\text{O}M_\text{C}}{M_\text{C}+2M_\text{O}}\ddot{X}_\text{O} = -k'X_\text{O}$$

$$M_\text{eff} = \frac{M_\text{O}M_\text{C}}{M_\text{C}+2M_\text{O}}.$$

(e) We want the angular frequency. From the differential equation in part (d) we recognize that $\ddot{X}_\text{O} = -(k'/M_\text{eff})X_\text{O}$

$$\omega = \sqrt{k'/M_\text{eff}} = \sqrt{\frac{k'}{\frac{M_\text{O}M_\text{C}}{M_\text{C}+2M_\text{O}}}} = \sqrt{\frac{k'(M_\text{C}+2M)}{M_\text{O}M_\text{C}}}.$$

(f) We want the frequency *f*.

$$f = \omega/2\pi = \frac{1}{2\pi}\sqrt{\frac{k'(M_\text{C}+2M)}{M_\text{O}M_\text{C}}}.$$

Using $k' = 1860$ N/m, $M_\text{O} = 16$ u, and $M_\text{C} = 12$ u, we get $f = 8.06 \times 10^{13}$ Hz.

EVALUATE: This frequency is much lower than that of visible light.

42.52. **IDENTIFY:** This problem deals with the energy levels of molecules.

SET UP: Follow the instructions with each part. To get five significant figures, we should use numbers of even greater precision.

EXECUTE: **(a)** We want the photon energies. Use $E = hc/\lambda$ to calculate the energies

$E = hc/\lambda = hc/(4.2680\ \mu\text{m}) = 0.29049$ eV.
$E = hc/(4.2753\ \mu\text{m}) = 0.290006$ eV.
$E = hc/(4.2826\ \mu\text{m}) = 0.289512$ eV.
$E = hc/(4.2972\ \mu\text{m}) = 0.288528$ eV.
$E = hc/(4.3046\ \mu\text{m}) = 0.288032$ eV.

(b) We want to know which one of the energies in part (a) is due to a transition from an $l = 0$ state. Eq. (42.9) gives the energy due to rotation and vibration. The selection rules are $\Delta l = \pm 1$ and $\Delta n = 1$.

$$E_{nl} = l(l+1)\frac{\hbar^2}{2I} + \left(n+\frac{1}{2}\right)\hbar\sqrt{\frac{k'}{m_\text{r}}}$$

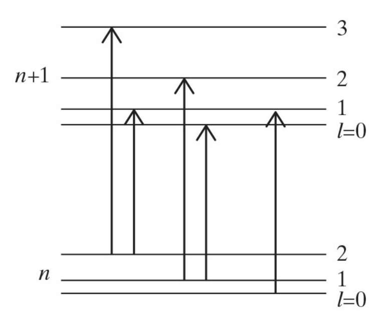

Figure 42.52

All the transitions are from the lowest energy states, which are $l = 0, 1, 2$. Figure 42.52 shows the five possible transitions from adjacent *n* states. The energy of a photon is equal to the energy difference between the two levels. Since Δn is the same for all these transitions, the energy difference between *rotational* states is what causes the different-energy photons. Therefore we need only look at the rotational energy differences between states. These are given by

$$\Delta E = E_{l_2} - E_{l_1} = [l_2(l_2+1) - l_1(l_1+1)]\frac{\hbar^2}{2I}$$

For the five transitions shown in Figure 42.52, the energy differences are

$$\Delta E_{0\to 1} = [1(1+1)-0]\frac{\hbar^2}{2I} = \frac{\hbar^2}{I}$$

$$\Delta E_{1\to 0} = [0-2]\frac{\hbar^2}{2I} = -\frac{\hbar^2}{I}$$

$$\Delta E_{1\to 2} = [2(2+1)-1(1+1)]\frac{\hbar^2}{2I} = \frac{2\hbar^2}{I}$$

$$\Delta E_{2\to 1} = [1(1+1)-2(2+1)]\frac{\hbar^2}{2I} = \frac{-2\hbar^2}{I}$$

$$\Delta E_{2\to 3} = [3(3+1)-2(2+1)]\frac{\hbar^2}{2I} = \frac{3\hbar^2}{I}$$

The total energy difference is due to Δl and Δn. The photon energy E is therefore $E = \Delta E_n + \Delta E_l$. For the l transition in this situation, we have the following:

$$E_{0\to 1} = \Delta E_n + \frac{\hbar^2}{I}$$

$$E_{1\to 0} = \Delta E_n - \frac{\hbar^2}{I}$$

$$E_{1\to 2} = \Delta E_n + \frac{2\hbar^2}{I}$$

$$E_{2\to 1} = \Delta E_n - \frac{2\hbar^2}{I}$$

$$E_{2\to 3} = \Delta E_n + \frac{3\hbar^2}{I}$$

Now rank the photon energies just calculated here and the photon energies calculated in part (a), from the lowest to the highest. By comparing the two rankings, we can tell which photon energy is due to a transition from an $l = 0$ state.

$$E_{2\to 1} = \Delta E_n - \frac{2\hbar^2}{I} \qquad 0.288032 \text{ eV}$$

$$E_{1\to 0} = \Delta E_n - \frac{\hbar^2}{I} \qquad 0.288528 \text{ eV}$$

$$E_{0\to 1} = \Delta E_n + \frac{\hbar^2}{I} \qquad 0.289512 \text{ eV}$$

$$E_{1\to 2} = \Delta E_n + \frac{2\hbar^2}{I} \qquad 0.290006 \text{ eV}$$

$$E_{2\to 3} = \Delta E_n + \frac{3\hbar^2}{I} \qquad 0.290503 \text{ eV}$$

From this list, we see that energy from the $l = 0$ state is $E_{0\to 1} = 0.289512$ eV.

(c) Using the results of part (b), we see that the second-highest energy states correspond, so $E_{1\to 0}$ = 0.288528 eV.

(d) Use the results from parts (b) and (c). ΔE_n is the same for both transitions.

$$l = 0 \to l = 1: \quad 0.289512 \text{ eV} = \frac{\hbar^2}{I} + \Delta E_n$$

$$l = 1 \to l = 0: \quad 0.288528 \text{ eV} = \frac{\hbar^2}{I} + \Delta E_n$$

Add the equations and use Eq. (42.9) to find ΔE_n. Then solve for the desired quantity.

$$0.289512 \text{ eV} + 0.288528 \text{ eV} = 2\Delta E_n = 2\hbar\sqrt{k'/m_r}$$

$$\hbar\sqrt{k'/m_r} = 0.289020 \text{ eV}.$$

(e) We want I. Subtract the two equations at the beginning of part (d) and solve for I, giving

$$I = 1.41\times10^{-46} \text{ kg}\cdot\text{m}^2.$$

(f) What is the mystery gas? Use the information in Figure 42.52 in the textbook to calculate the moment of inertia of each molecule. Then compare these with what we found in part (e). Start with N_2.

$$I = m_r r_0^2 = \frac{m_1 m_2}{m_1+m_2}r_0^2 = \frac{(14 \text{ u})(14 \text{ u})}{28 \text{ u}}(110 \text{ pm})^2 = 1.41\times10^{-46} \text{ kg}\cdot\text{m}^2.$$

This result matches the moment of inertia we found in part (e), so the gas is N_2.

(g) In part (f) we saw that m_r = (14 u)(14 u)/(28 u) = 7 u.

(h) Use the result from part (d) and solve for the spring constant, giving 2241 N/m.

EVALUATE: The spring constant we found would be a very large one for the types of springs found in most physics labs.

42.53. **IDENTIFY** and **SET UP:** $p = -\dfrac{dE_{\text{tot}}}{dV}$. Relate E_{tot} to E_{F0} and evaluate the derivative.

EXECUTE: **(a)** $\dfrac{dE_{\text{tot}}}{dV} = \dfrac{3}{5}\left(\dfrac{3^{2/3}\pi^{4/3}\hbar^2}{2m}\right)N^{5/3}\left(-\dfrac{2}{3}V^{-5/3}\right)$, so $p = \left(\dfrac{3^{2/3}\pi^{4/3}\hbar^2}{5m}\right)\left(\dfrac{N}{V}\right)^{5/3}$, as was to be shown.

(b) $N/V = 8.45\times10^{28} \text{ m}^{-3}$.

$$p = \left(\frac{3^{2/3}\pi^{4/3}(1.055\times10^{-34} \text{ J}\cdot\text{s})^2}{5(9.109\times10^{-31} \text{ kg})}\right)(8.45\times10^{28} \text{ m}^{-3})^{5/3} = 3.81\times10^{10} \text{ Pa} = 3.76\times10^5 \text{ atm}.$$

EVALUATE: **(c)** Normal atmospheric pressure is about 10^5 Pa, so these pressures are extremely large. The electrons are held in the metal by the attractive force exerted on them by the copper ions.

42.54. **IDENTIFY** and **SET UP:** From Problem 42.53, $p = \dfrac{3^{2/3}\pi^{4/3}\hbar^2}{5m}\left(\dfrac{N}{V}\right)^{5/3}$. Use this expression to calculate dp/dV.

EXECUTE: **(a)** $B = -V\dfrac{dp}{dV} = -V\left[\dfrac{5}{3}\cdot\dfrac{3^{2/3}\pi^{4/3}\hbar^2}{5m}\cdot\left(\dfrac{N}{V}\right)^{2/3}\left(\dfrac{-N}{V^2}\right)\right] = \dfrac{5}{3}p.$

(b) $\dfrac{N}{V} = 8.45\times10^{28} \text{ m}^{-3}$. $B = \dfrac{5}{3}\cdot\dfrac{3^{2/3}\pi^{4/3}\hbar^2}{5m}(8.45\times10^{28}\text{m}^{-3})^{5/3} = 6.33\times10^{10}$ Pa.

EVALUATE: **(c)** The fraction of B due to the free electrons is $\dfrac{6.33\times10^{10} \text{ Pa}}{1.4\times10^{11} \text{ Pa}} = 0.45$. The copper ions themselves make up the remaining fraction.

42.55. **IDENTIFY** and **SET UP:** Follow the steps specified in the problem.

EXECUTE: **(a)** $E_{\text{F0}} = \dfrac{3^{2/3}\pi^{4/3}\hbar^2}{2m}\left(\dfrac{N}{V}\right)^{2/3}$. Let $E_{\text{F0}} = \dfrac{1}{100}mc^2$.

$$\left(\frac{N}{V}\right) = \left[\frac{2m^2c^2}{(100)3^{2/3}\pi^{4/3}\hbar^2}\right]^{3/2} = \frac{2^{3/2}m^3c^3}{100^{3/2}3\pi^2\hbar^3} = \frac{2^{3/2}m^3c^3}{3000\pi^2\hbar^3} = 1.67\times10^{33} \text{ m}^{-3}.$$

(b) $\dfrac{8.45\times10^{28} \text{ m}^{-3}}{1.67\times10^{33} \text{ m}^{-3}} = 5.06\times10^{-5}$. Since the real concentration of electrons in copper is less than one part in 10^{-4} of the concentration where relativistic effects are important, it is safe to ignore relativistic effects for most applications.

(c) The number of electrons is $N_e = \dfrac{6(2\times10^{30}\ \text{kg})}{1.99\times10^{-26}\ \text{kg}} = 6.03\times10^{56}.$ The concentration is

$$\frac{N_e}{V} = \frac{6.03\times10^{56}}{\frac{4}{3}\pi(6.00\times10^{6}\ \text{m})^3} = 6.66\times10^{35}\ \text{m}^{-3}.$$

EVALUATE: **(d)** Comparing this to the result from part (a) $\dfrac{6.66\times10^{35}\ \text{m}^{-3}}{1.67\times10^{33}\ \text{m}^{-3}} \cong 400,$ so relativistic effects will be very important.

42.56. **IDENTIFY** and **SET UP:** The sensitivity is defined as $\Delta V/\Delta T$.

EXECUTE: From the graph shown with the introduction, we see that for a current of 0.1 A (100 mA), the voltage at 25°C is about 0.75 V, and at 150°C it is about 0.55 V. Therefore the sensitivity is $\dfrac{\Delta V}{\Delta T} = \dfrac{0.55\ \text{V} - 0.75\ \text{V}}{150°\text{C} - 25°\text{C}} = -1.6\ \text{mV/C°} \approx -2.0\ \text{mV/C°}.$ Therefore choice (d) is correct.

EVALUATE: If the temperature changes by 10 C°, V changes by about 20 mV, which can be significant.

42.57. **IDENTIFY** and **SET UP:** As the temperature increases, the electrons gain energy.

EXECUTE: As T increases, more electrons gain enough energy to jump into the conduction band, so for a given voltage, more current will flow at a higher temperature than at a lower temperature. Therefore choice (b) is correct.

EVALUATE: For ordinary resistors, increasing their temperature increases their resistance, so less current would flow.

42.58. **IDENTIFY** and **SET UP:** On the graph shown with the introduction, draw a vertical line between the two curves. This line represents a constant voltage.

EXECUTE: For V greater than about 0.2 V, the current at 150°C is greater than at 25°C. So increasing the temperature at a constant voltage increases the current, which makes choice (b) correct.

EVALUATE: This result is consistent with what we found in Passage Problem 42.57.

43

NUCLEAR PHYSICS

VP43.4.1. **IDENTIFY:** This problem is about the binding energy of an O-16 nucleus.

SET UP and **EXECUTE:** **(a)** We want the mass defect ΔM. Use the numerical values given in the text and Table 43.2. For O-16, $Z = 8$ and $A = 16$ so $N = 8$.

$\Delta M = ZM_{\text{H}} + Nm_{\text{n}} - {}^{A}_{Z}M.$

$\Delta M = 8(1.007825\text{ u}) - 8(1.008655\text{ u}) - 15.994915\text{ u} = 0.137005\text{ u}.$

(b) We want the binding energy. $E_{\text{B}} = \Delta Mc^2 = (0.137005\text{ u})(931.5\text{ MeV/u}) = 127.6\text{ MeV}.$

(c) We want the binding energy per nucleon. O-16 has 16 nucleons, so

$$E_{\text{B}}/\text{nucleon} = (127.6\text{ MeV})/16 = 7.976\text{ MeV/nucleon}.$$

EVALUATE: From the graph in Figure 43.2, we see that O-16 is more tightly bound that C-12 but less so than Ni-62.

VP43.4.2. **IDENTIFY:** This problem is about the energy of the Cu-63 nucleus.

SET UP and **EXECUTE:** We know that the mass defect is 0.5919378 u. **(a)** The binding energy E_{B} is the energy of the mass defect. $E_{\text{B}} = (0.5919378\text{ u})(931.5\text{ MeV/u}) = 551.4\text{ MeV}.$

(b) $E_{\text{B}}/\text{nucleon} = (551.4\text{ MeV})/(63\text{ nucleons}) = 8.752\text{ MeV/nucleon}.$

(c) We want the mass of the Cu-63 atom. Use Eq. (43.10) with $Z = 29$ and $A = 63$, so $N = 34$.

EVALUATE: Note that the C-63 mass is about 63 u, but *not quite*.

VP43.4.3. **IDENTIFY:** This problem is about nuclear binding energy.

SET UP: The binding energy per nucleon is E_{B}/A where E_{B} is the energy of the mass defect. Use the given mass defects to calculate E_{B}.

EXECUTE: **(a)** As-75. $E_{\text{B}}/A = (0.7005604\text{ u})(931.5\text{ MeV/u})/75 = 8.701\text{ MeV/nucleon}.$

(b) Sm-150. Use the same method as in (a) with $A = 150$, giving $E_{\text{B}}/A = 8.262\text{ MeV/nucleon}.$

(c) Ra-225. $A = 225$ gives $E_{\text{B}}/A = 7.668\text{ MeV/nucleon}.$

(d) As A increases from 75 to 225, E_{B}/A decreases from 8.701 MeV/nucleon to 7.668 MeV/nucleon. This behavior agrees with Figure 43.2.

EVALUATE: Note that the *total* binding energy increases as A increases, but the binding energy *per nucleon* decreases.

VP43.4.4. **IDENTIFY:** In this problem, we use the semiempirical mass formula to calculate the binding energy.

SET UP: Eq. (43.11) gives the formula and the constants $C_1, C_2, \ldots, C_5$ are given following it. We follow the procedure of Example 43.4.

EXECUTE: **(a)** Ru-100. $A = 100$, $Z = 44$. Using Eq. (43.11) gives the following terms.

$C_1A = (15.75\text{ MeV})(100) = 1575$

$-C_2A^{2/3} = -(17.80\text{ MeV})(100^{2/3}) = -383.5$

$-C_3Z(Z-1)/A^{1/3} = -(0.7100\text{ MeV})(44)(43)/(100^{1/3}) = -289.4\text{ MeV}$

$-C_4(A-2Z)^2/A = -(23.69\text{ MeV})(100-88)^2/(100) = -34.11\text{ MeV}$

$+C_5A^{-4/3} = (39\text{ MeV})(100^{-4/3}) = 0.084\text{ MeV}.$

Adding all these terms gives E_B = 868.1 MeV. E_B/A = (868.1 MeV)/100 = 8.681 MeV/nucleon.
(b) Hg-200. A = 200, Z = 80. Use the same procedure as in part (a), giving E_B = 1584 MeV, E_B/A = (1584 MeV)/(200) = 7.922 MeV/nucleon.
EVALUATE: **(c)** From Figure 43.2: For A = 100, $E_B/A \approx$ 8.66 MeV/nucleon, and we got 8.681 MeV/nucleon.
For A = 200, $E_B/A \approx$ 7.85 MeV/nucleon, and we got 79.22 MeV/nucleon. Our results agree closely with those in the figure.

VP43.7.1. **IDENTIFY:** This problem is about energy in radioactive decay.
SET UP and **EXECUTE:** **(a)** We want the energy released. Refer to the decay shown in the problem. Using the given masses, the mass difference is 241.056827 u – (237.048172 u + 4.002603 u) = 0.0060520 u. The energy released is the energy of this mass, which is given by (0.006052 u)(931.5 MeV/u) = 5.637 MeV.
(b) We want the kinetic energy of the alpha particle. The rest energy of He is (4 u)(931.5 MeV/u) = 3726 MeV, which is much greater than the energy released. Therefore we do not need to use relativity. Momentum conservation gives $m_\alpha v_\alpha = m_{Np}v_{Np}$, so $v_\alpha/v_{Np} = m_{Np}/m_\alpha$. Using the masses gives v_{Np} = $(4.003/237.0)v_\alpha = 0.016890v_\alpha$. Energy conservation gives $K_\alpha + K_{Np}$ = 5.637 MeV. Using $K = \frac{1}{2}mv^2$ and taking the ratio of kinetic energies gives K_α/K_{Np} = 59.22. Adding the kinetic energies gives K_α + K_α/59.22
= 5.637 MeV. K_α = 5.543 MeV.
(c) We want the speed of the alpha particle. Use the result from (b) and $K = \frac{1}{2}mv^2$ and solve for v, giving $v_\alpha = 1.63 \times 10^7$ m/s.
EVALUATE: v/c = 0.16/3.0 = 0.053, so v is about 5% the speed of light, which means that it was OK to neglect relativity.

VP43.7.2. **IDENTIFY:** This problem is about the nuclear decay of Be-8 to two alpha particles.
SET UP: First find the mass defect and use it to find the energy released. The alpha particles each get one-half of this energy.
EXECUTE: **(a)** We want the kinetic energy. The mass defect is $m_{Be} - 2m_{He}$, which gives [8.0053051 u – 2(4.0026033 u)](931.5 MeV/u) = 0.09175 MeV. Each alpha particle gets half of this, so K_α = 0.0459 MeV.
(b) We want the speed of the alpha particles. The rest energy of the alpha is (4.0026 u)(931.5 MeV/u) = 3730 MeV, which is much greater than its kinetic energy. So we do not need to use relativity. Use $K = \frac{1}{2}mv^2$ with K = 0.0459 MeV, giving $v_\alpha = 1.49 \times 10^6$ m/s.
EVALUATE: v/c = 0.0149/3.0 = 0.00497, so $v \ll c$. Our neglect of relativity was justified.

VP43.7.3. **IDENTIFY:** This problem is about β^- decay.
SET UP: β^- decay is possible if the mass of the original neutral atom is greater than the mass of the final atom. The energy released is the energy of the difference in mass.
EXECUTE: **(a)** The mass of Be-12 is greater than the mass of B-12, so this decay is possible. The energy released is E = (12.026922 u – 12.014353 u)(931.5 MeV/u) = 11.71 MeV.
(b) The mass of Ar-33 is greater than the mass of Cl-33, so this decay is not possible.
(c) The mass of Br-82 is greater than the mass of Kr-82, so this decay is possible. As in part (a), E = (81.9168018 u – 81.9134812 u)(931.5 MeV/u) = 3.093 MeV.
EVALUATE: The greater the mass difference, the greater the energy that is released.

VP43.7.4. **IDENTIFY:** This problem is about β^+ decay.
SET UP: β^+ decay is possible if the mass of the original neutral atom is greater than the mass of the final atom by twice the electron mass. The mass of the electron is 0.000548580 u, so the mass of the original atom must be greater than that of the final atom by 2(0.000548580 u) = 0.001097160 u. The energy released is the energy of the difference in mass minus two electron masses.

EXECUTE: (a) The mass difference is 45.960198 – 45.952627 u = 0.0075710 u. This difference is greater than twice the electron mass, so the decay is possible. The energy released is

$$E = (0.0075710\text{ u} - 0.001097160\text{ u})(931.5\text{ MeV/u}) = 6.030\text{ MeV}.$$

(b) Δm = 133.908514 u – 133.904508 u = 0.0040060 u > $2m_e$, so the decay is possible. The energy is E = (0.0040060 u – 0.00109716 u)(931.5 MeV/u) = 2.710 MeV.

(c) Δm = 66.928202 u – 66.9271275 u = 0.0010745 u < $2m_e$, so β^+ decay is not possible. The original atom's mass is greater than that of the final atom, so electron capture is possible.

EVALUATE: If the mass of the original atom is greater than the mass of the final atom, then β^+ decay and electron capture are *both* possible, so both may occur. A number of radionuclides decay by more than one mode.

VP43.9.1. IDENTIFY: This problem deals with radioactive decay. The half-life is $T_{1/2}$ = 15.0 h and the initial activity is dN/dt = –1.60 μCi.

SET UP and EXECUTE: (a) $T_{\text{mean}} = T_{1/2}/(\ln 2)$ = (15.0 h)/(ln 2) = 21.6 h = 7.79×10^4 s.

(b) $\lambda = (\ln 2)/T_{1/2}$ = (ln 2)/(15.0 h) = $4.621 \times 10^{-2}\text{ h}^{-1} = 1.28 \times 10^{-5}\text{ s}^{-1}$.

(c) We want the initial number N_0 of Na-24 nuclei. We know the initial activity, so we make use of that.

$$N = N_0 e^{-\lambda t}$$

$$dN/dt = -\lambda N_0 e^{-\lambda t} = -\lambda N_0$$

$$N_0 = -\frac{1}{\lambda}\frac{dN}{dt} = -\frac{1}{1.28\times 10^{-5}\text{ s}^{-1}}(-1.50\ \mu\text{Ci})(3.70\times 10^{10}\text{ s}^{-1}) = 4.32\times 10^{9}.$$

(d) We want dN/dt after 24.0 h. From our work in part (c), we can see that

$$dN/dt = dN/dt)_0\, e^{-\lambda t} = (1.50\ \mu\text{Ci})\, e^{-(0.04621\text{ h}^{-1})(24.0\text{ h})} = 0.495\ \mu\text{Ci}.$$

EVALUATE: In 15 h, dN/dt would be 0.75 μCi, and our result in part (d) is less than that, so it is reasonable.

VP43.9.2. IDENTIFY: This problem deals with radioactive decay. The half-life is $T_{1/2}$ = 35.0 h and the initial activity is dN/dt = –0.514 μCi.

SET UP and EXECUTE: (a) $\lambda = (\ln 2)/T_{1/2}$ = (ln 2)/(35.0 h) = $1.98 \times 10^{-2}\text{ h}^{-1} = 5.50 \times 10^{-6}\text{ s}^{-1}$.

(b) We want the present number N_0 of Nb-95 nuclei.

$$N = N_0 e^{-\lambda t}$$

$$dN/dt = -\lambda N_0 e^{-\lambda t} = -\lambda N_0$$

Call t = 0 the present instant when dN/dt = –0.514 μCi. Solve the above equation for N_0.

$$N_0 = -\frac{1}{\lambda}\frac{dN}{dt} = -\frac{1}{5.50\times 10^{-6}\text{ s}^{-1}}(-0.514\ \mu\text{Ci})(3.70\times 10^{10}\text{ s}^{-1}) = 3.46\times 10^{9}.$$

(c) We want the initial number of Nb-95 nuclei. The 3.46×10^9 nuclei from part (b) is 23.8% of the original number of nuclei. So $0.238N_0 = 3.46 \times 10^9$, which gives $N_0 = 1.45 \times 10^{10}$.

(d) We want the time to now. Solve for t and use the results we have found.

$$N = N_0 e^{-\lambda t}$$

$$t = -\frac{\ln(N/N_0)}{\lambda} = \frac{\ln\left(\dfrac{3.46\times 10^{9}}{1.45\times 10^{10}}\right)}{0.0198\text{ h}^{-1}} = 72.5\text{ h}.$$

EVALUATE: The number of Mo-95 nuclei present now is $(0.762)(1.45 \times 10^{10}) = 1.11 \times 10^{10}$. The sum of nuclei now is $1.11 \times 10^{10} + 3.46 \times 10^9 = 1.45 \times 10^{10}$, which agrees with our result in (c).

VP43.9.3. **IDENTIFY:** We are dealing with radioactive decay. The initial activity is 0.415 μCi, and 45.0 s later it is 0.121 μCi.

SET UP and EXECUTE: **(a)** We want the decay constant and half-life. If we call R the activity, we have seen that it decreases exponentially. Use this fact and solve for the decay constant and then use it to find the half-life.

$$R = R_0 e^{-\lambda t}$$

$$\lambda = -\frac{\ln(R/R_0)}{t} = -\frac{\ln\left(\dfrac{0.121\ \mu\text{Ci}}{0.425\ \mu\text{Ci}}\right)}{45.0\text{ s}} = 0.0279\text{ s}^{-1}.$$

$T_{1/2} = (\ln 2)/\lambda = (\ln 2)/(0.279\text{ s}^{-1}) = 24.8$ s.

(b) We want the number of nuclei in an excited state. These are the nuclei that give off the radiation, so we want to find the number of undecayed nuclei initially and 45.0 s later.

Initially:

$$dN/dt = -\lambda N_0 e^{-\lambda t} = -\lambda N_0$$

$$(-0.425\ \mu\text{Ci})(3.70 \times 10^{10}\text{ s}^{-1}) = -(0.0279\text{ s}^{-1})N_0$$

$$N_0 = 5.63 \times 10^5.$$

After 45.0 s: Using the same approach gives $(-0.121\ \mu\text{Ci})(3.70 \times 10^{10}\text{ s}^{-1}) = -(0.0279\text{ s}^{-1})N_0$

$N_0 = 1.60 \times 10^5$.

EVALUATE: The number at 45.0 s is less than the initial number, so our result is reasonable.

VP43.9.4. **IDENTIFY:** This problem is about carbon-14 dating.

SET UP: The half-life of C-14 is 5730 y. If we call R the activity level per gram, it follows from previous work that $R = R_0 e^{-\lambda t}$.

EXECUTE: **(a)** We want the age of the sample. The activity per unit mass that you detect now is 113 decays per 20 min per 0.510 g of carbon. So R = [(113 decays)/(20 min)]/(0.510 g) = 0.18464 Bq/g. Use $R = R_0 e^{-\lambda t}$ with $\lambda = (\ln 2)/T_{1/2}$ and solve for t.

$$t = \frac{\ln(R/R_0)}{\lambda} = -\frac{T_{1/2}\ln(R/R_0)}{\ln 2} = -\frac{(5730\text{ y})\ln\left(\dfrac{0.18464\text{ Bq/g}}{0.255\text{ Bq/g}}\right)}{45.0\text{ s}} = 2670\text{ y}.$$

(b) We want the current number of C-14 nuclei. Call $t = 0$ the present time. In your sample, the present activity is (113 decays)/(20 min) = 0.094167 Bq. At $t = 0$ (the present time), we have

$$N_0 = \frac{1}{\lambda}\frac{dN}{dt} = -\frac{T_{1/2}}{\ln 2}(-0.094167\text{ Bq}) = \frac{(5730\text{ y})(0.094167\text{ Bq})}{\ln 2} = 2.46\times 10^{10}.$$

EVALUATE: The age of your sample is less than one half-life, so its activity (0.18464 Bq/g) should be greater than half the original activity (0.255 Bq/g), which is what we have found.

43.1. **IDENTIFY and SET UP:** The pre-subscript is Z, the number of protons. The pre-superscript is the mass number A. $A = Z + N$, where N is the number of neutrons.

EXECUTE: **(a)** $^{28}_{14}\text{Si}$ has 14 protons and 14 neutrons.

(b) $^{85}_{37}\text{Rb}$ has 37 protons and 48 neutrons.

(c) $^{205}_{81}\text{Tl}$ has 81 protons and 124 neutrons.

EVALUATE: The number of protons determines the chemical element.

43.2. **IDENTIFY:** Calculate the spin magnetic energy shift for each spin state of the 1s level. Calculate the energy splitting between these states and relate this to the frequency of the photons.

SET UP: When the spin component is parallel to the field the interaction energy is $U = -\mu_z B$. When the spin component is antiparallel to the field the interaction energy is $U = +\mu_z B$. The transition energy for a transition between these two states is $\Delta E = 2\mu_z B$, where $\mu_z = 2.7928\mu_n$. The transition energy is related to the photon frequency by $\Delta E = hf$, so $2\mu_z B = hf$.

EXECUTE: $B = \dfrac{hf}{2\mu_z} = \dfrac{(6.626\times10^{-34}\ \text{J}\cdot\text{s})(22.7\times10^{6}\ \text{Hz})}{2(2.7928)(5.051\times10^{-27}\ \text{J/T})} = 0.533\ \text{T}$

EVALUATE: This magnetic field is easily achievable. Photons of this frequency have wavelength $\lambda = c/f = 13.2$ m. These are radio waves.

43.3. **(a) IDENTIFY:** Find the energy equivalent of the mass defect.

SET UP: A $^{11}_{5}\text{B}$ atom has 5 protons, $11-5=6$ neutrons, and 5 electrons. The mass defect therefore is $\Delta M = 5m_\text{p} + 6m_\text{n} + 5m_\text{e} - M(^{11}_{5}\text{B})$.

EXECUTE: $\Delta M = 5(1.0072765\ \text{u}) + 6(1.0086649\ \text{u}) + 5(0.0005485799\ \text{u}) - 11.009305\ \text{u} = 0.08181\ \text{u}$.

The energy equivalent is $E_\text{B} = (0.08181\ \text{u})(931.5\ \text{MeV/u}) = 76.21\ \text{MeV}$.

(b) IDENTIFY and **SET UP:** Eq. (43.11): $E_\text{B} = C_1A - C_2A^{2/3} - C_3Z(Z-1)/A^{1/3} - C_4(A-2Z)^2/A$.

The fifth term is zero since Z is odd but N is even. $A = 11$ and $Z = 5$.

EXECUTE:

$E_\text{B} = (15.75\ \text{MeV})(11) - (17.80\ \text{MeV})(11)^{2/3} - (0.7100\ \text{MeV})5(4)/11^{1/3} - (23.69\ \text{MeV})(11-10)^2/11.$

$$E_\text{B} = +173.25\ \text{MeV} - 88.04\ \text{MeV} - 6.38\ \text{MeV} - 2.15\ \text{MeV} = 76.68\ \text{MeV}.$$

The percentage difference between the calculated and measured E_B is

$$\frac{76.68\ \text{MeV} - 76.21\ \text{MeV}}{76.21\ \text{MeV}} = 0.6\%.$$

EVALUATE: Eq. (43.11) has a greater percentage accuracy for ^{62}Ni. The semi-empirical mass formula is more accurate for heavier nuclei.

43.4. **IDENTIFY:** The binding energy E_B is the difference between the energy of the constituent nuclides and final nuclide, converted to energy units.

SET UP: Use the masses in Table 43.2 and m_n = 1.008665 u for the neutron. The masses in Table 43.2 are for neutral atoms and therefore include the mass of the electrons. 1 u is equivalent to 931.5 MeV.

For $^{11}_{5}\text{B}$: $E_\text{B}(\text{B-11}) = 5m_\text{H} + 6m_\text{n} - m_\text{B-11}$.

For $^{11}_{6}\text{C}$: $E_\text{B}(\text{C-11}) = 6m_\text{H} + 5m_\text{n} - m_\text{C-11}$.

EXECUTE: **(a)** $^{11}_{5}\text{B}$: E_B = [5(1.007825 u) + 6(1.008665 u) – 11.009305 u](931.5 MeV/u) = 76.21 MeV.

$^{11}_{6}\text{C}$: E_B = [6(1.007825 u) + 5(1.008665 u) – 11.011434 u](931.5 MeV/u) = 73.44 MeV.

EVALUATE: **(b)** The $^{11}_{5}\text{B}$ has a larger binding energy than the $^{11}_{6}\text{C}$. This is probably due to the fact that $^{11}_{5}\text{B}$ has one fewer proton and one more neutron than $^{11}_{6}\text{C}$. The electrical repulsion between protons tends to decrease binding energy while the extra neutron tends to increase it without a corresponding electrical repulsion.

43.5. **IDENTIFY:** The binding energy of the nucleus is the energy of its constituent particles minus the energy of the carbon-12 nucleus.

SET UP: In terms of the masses of the particles involved, the binding energy is $E_\text{B} = (6m_\text{H} + 6m_\text{n} - m_{\text{C}-12})c^2$.

EXECUTE: **(a)** Using the values from Table 43.2, we get

$$E_\text{B} = [6(1.007825\ \text{u}) + 6(1.008665\ \text{u}) - 12.000000\ \text{u}](931.5\ \text{MeV/u}) = 92.16\ \text{MeV}.$$

(b) The binding energy per nucleon is $(92.16\ \text{MeV})/(12\ \text{nucleons}) = 7.680\ \text{MeV/nucleon}$.

(c) The energy of the C-12 nucleus is $(12.0000\text{ u})(931.5\text{ MeV/u}) = 11178\text{ MeV}$. Therefore the percent of the mass that is binding energy is $\dfrac{92.16\text{ MeV}}{11178\text{ MeV}} = 0.8245\%$.

EVALUATE: The binding energy of 92.16 MeV binds 12 nucleons. The binding energy per nucleon, rather than just the total binding energy, is a better indicator of the strength with which a nucleus is bound.

43.6. **IDENTIFY:** The mass defect is the total mass of the constituents minus the mass of the atom.

SET UP: 1 u is equivalent to 931.5 MeV. ${}^{238}_{92}\text{U}$ has 92 protons, 146 neutrons and 238 nucleons.

EXECUTE: **(a)** $146m_\text{n} + 92m_\text{H} - m_\text{U} = 1.93\text{ u}$.

(b) $1.80\times10^3\text{ MeV}$.

(c) 7.57 MeV per nucleon (using 931.5 MeV/u and 238 nucleons).

EVALUATE: The binding energy per nucleon we calculated agrees with Figure 43.2 in the textbook.

43.7. **IDENTIFY:** This problem is about the binding energy of the atomic nucleus.

SET UP and **EXECUTE:** The target variable is the mass of a neutral Fe-56 atom. Since the atom is neutral, it contains all of its electrons. Use Eq. (43.10) and solve for the mass of Fe-56.

$$ {}^{56}_{26}M = ZM_\text{H} + Nm_\text{n} - E_\text{B}/c^2 $$

$$ {}^{56}_{26}M = 26(1.007825\text{ u}) + 30(1.008665\text{ u}) - \left[(8.79\text{ MeV})(56)/c^2\right]\left(\frac{1\text{ u}}{931.5\text{ MeV}/c^2}\right) = 55.935\text{ u}. $$

EVALUATE: If there were no binding energy, the mass would be $26M_\text{H} + 30m_\text{n} = 56.463$ u. The binding energy makes a detectable difference in the mass of the atom.

43.8. **IDENTIFY:** The binding energy E_B is the difference between the energy of the constituent nuclides and final nuclide, converted to energy units.

SET UP: Use the masses in Table 43.2 and $m_\text{n} = 1.008665$ u for the neutron. The masses in Table 43.2 are for neutral atoms and therefore include the mass of the electrons. 1 u is equivalent to 931.5 MeV.

For an alpha particle: ${}^{4}_{2}\text{He}$: $E_\text{B}(\alpha) = 2m_\text{H} + 2m_\text{n} - m_\text{He-4}$.

For ${}^{12}_{6}\text{C}$: $E_\text{B}(\text{C-12}) = 6m_\text{H} + 6m_\text{n} - m_\text{C-12}$.

EXECUTE: ${}^{4}_{2}\text{He}$: E_B = [2(1.007825 u) + 2(1.008665 u) – 4.002603 u](931.5 MeV/u) = 28.296 MeV, so 3 times the binding energy of the alpha particle is 3(28.296 MeV) = 84.889 MeV.

${}^{12}_{6}\text{C}$: E_B = [6(1.007825 u) + 6(1.008665 u) – 12.000000 u](931.5 MeV/u) = 92.163 MeV.

EVALUATE: The binding energy of ${}^{12}_{6}\text{C}$ is greater than 3 times the binding energy of an alpha particle. This is reasonable since in addition to binding individual alpha particles, it takes additional energy to bind three of them in the nucleus to form carbon.

43.9. **IDENTIFY:** Conservation of energy tells us that the initial energy (photon plus deuteron) is equal to the energy after the split (kinetic energy plus energy of the proton and neutron). Therefore the kinetic energy released is equal to the energy of the photon minus the binding energy of the deuteron.

SET UP: The binding energy of a deuteron is 2.224 MeV and the energy of the photon is $E = hc/\lambda$. Kinetic energy is $K = \frac{1}{2}mv^2$.

EXECUTE: **(a)** The energy of the photon is

$$ E_\text{ph} = \frac{hc}{\lambda} = \frac{(6.626\times10^{-34}\text{ J}\cdot\text{s})(3.00\times10^8\text{ m/s})}{3.50\times10^{-13}\text{ m}} = 5.68\times10^{-13}\text{ J}. $$

The binding of the deuteron is $E_\text{B} = 2.224\text{ MeV} = 3.56\times10^{-13}\text{ J}$. Therefore the kinetic energy is

$$ K = (5.68 - 3.56)\times10^{-13}\text{ J} = 2.12\times10^{-13}\text{ J} = 1.32\text{ MeV}. $$

(b) The particles share the energy equally, so each gets half. Solving the kinetic energy for v gives

$$v=\sqrt{\frac{2K}{m}}=\sqrt{\frac{2(1.06\times10^{-13}\ \text{J})}{1.6605\times10^{-27}\ \text{kg}}}=1.13\times10^{7}\ \text{m/s}.$$

EVALUATE: Considerable energy has been released, because the particle speeds are in the vicinity of the speed of light.

43.10. **IDENTIFY:** The mass defect is the total mass of the constituents minus the mass of the atom.

SET UP: 1 u is equivalent to 931.5 MeV. ${}^{14}_{7}\text{N}$ has 7 protons and 7 neutrons. ${}^{4}_{2}\text{He}$ has 2 protons and 2 neutrons.

EXECUTE: **(a)** $7(m_\text{n}+m_\text{H})-m_\text{N}=0.112\ \text{u},$ which is 105 MeV, or 7.48 MeV per nucleon.

(b) Similarly, $2(m_\text{H}+m_\text{n})-m_\text{He}=0.03038\ \text{u}=28.3\ \text{MeV},$ or 7.07 MeV per nucleon.

EVALUATE: **(c)** The binding energy per nucleon is a little less for ${}^{4}_{2}\text{He}$ than for ${}^{14}_{7}\text{N}.$ This is in agreement with Figure 43.2 in the textbook.

43.11. **IDENTIFY:** We are looking at the decay of C-11.

SET UP and **EXECUTE:** **(a)** In positron decay, a proton changes to a neutron and an electron. So the number of protons decreases from 6 to 5 and the number of neutrons increases from 5 to 6. So the daughter nucleus contains 5 protons and 6 neutrons.

(b) For positron decay to occur, the mass of the parent must be at least two electron masses greater than the mass of the daughter. The daughter nucleus has 5 protons, so it is boron (B). The decay is

$${}^{11}_{6}\text{C}\rightarrow{}^{11}_{5}\text{B}+\beta^{+}+\nu_\text{e}.$$

Use Table 43.2 for the mass of boron and m_e = 0.000548580 u. The initial mass is 11.011433 u and the final mass is 11.009305 u + 2(0.000548580 u) = 11.01040216 u. The difference in mass is 11.01040216 u – 11.011433 u = –0.001030840 u. The energy released is the energy of the lost mass, which is (0.001030840 u)(931.5 MeV/u) = 0.960 MeV.

EVALUATE: Notice that we need to use *twice* the mass of the positron for positron decay.

43.12. **IDENTIFY:** Compare the total mass on each side of the reaction equation. Neglect the masses of the neutrino and antineutrino.

SET UP: 1 u is equivalent to 931.5 MeV.

EXECUTE: **(a)** The energy released is the energy equivalent of $m_\text{n}-m_\text{p}-m_\text{e}=8.40\times10^{-4}\ \text{u},$ or 783 keV.

(b) $m_\text{n}>m_\text{p},$ and the decay is not possible.

EVALUATE: β^- and β^+ particles have the same mass, equal to the mass of an electron.

43.13. **IDENTIFY:** In each case determine how the decay changes A and Z of the nucleus. The β^+ and β^- particles have charge but their nucleon number is $A=0.$

(a) SET UP: α-decay: Z decreases by $2, A=N+Z$ decreases by 4 (an α particle is a ${}^{4}_{2}\text{He}$ nucleus).

EXECUTE: ${}^{239}_{94}\text{Pu}\rightarrow{}^{4}_{2}\text{He}+{}^{235}_{92}\text{U}.$

(b) SET UP: β^- decay: Z increases by $1, A=N+Z$ remains the same (a β^- particle is an electron, ${}^{0}_{-1}\text{e}$).

EXECUTE: ${}^{24}_{11}\text{Na}\rightarrow{}^{0}_{-1}\text{e}+{}^{24}_{12}\text{Mg}.$

(c) SET UP: β^+ decay: Z decreases by $1, A=N+Z$ remains the same (a β^+ particle is a positron, ${}^{0}_{+1}\text{e}$).

EXECUTE: ${}^{15}_{8}\text{O}\rightarrow{}^{0}_{+1}\text{e}+{}^{15}_{7}\text{N}.$

EVALUATE: In each case the total charge and total number of nucleons for the decay products equals the charge and number of nucleons for the parent nucleus; these two quantities are conserved in the decay.

43.14. **IDENTIFY:** The energy released is equal to the mass defect of the initial and final nuclei.

SET UP: The mass defect is equal to the difference between the initial and final masses of the constituent particles.

EXECUTE: **(a)** The mass defect is $238.050788 \text{ u} - 234.043601 \text{ u} - 4.002603 \text{ u} = 0.004584 \text{ u}$. The energy released is $(0.004584 \text{ u})(931.5 \text{ MeV/u}) = 4.270 \text{ MeV}$.

(b) Take the ratio of the two kinetic energies, using the fact that $K = p^2/2m$:

$$\frac{K_{\text{Th}}}{K_\alpha} = \frac{\frac{p_{\text{Th}}^2}{2m_{\text{Th}}}}{\frac{p_\alpha^2}{2m_\alpha}} = \frac{m_\alpha}{m_{\text{Th}}} = \frac{4}{234}.$$

The kinetic energy of the Th is

$$K_{\text{Th}} = \frac{4}{234+4}K_{\text{Total}} = \frac{4}{238}(4.270 \text{ MeV}) = 0.07176 \text{ MeV} = 1.148\times10^{-14} \text{ J}.$$

Solving for v in the kinetic energy gives

$$v = \sqrt{\frac{2K}{m}} = \sqrt{\frac{2(1.148\times10^{-14} \text{ J})}{(234.043601)(1.6605\times10^{-27} \text{ kg})}} = 2.431\times10^5 \text{ m/s}.$$

EVALUATE: As we can see by the ratio of kinetic energies in part (b), the alpha particle will have a much higher kinetic energy than the thorium.

43.15. **IDENTIFY:** This problem is about β^+ decay.

SET UP and **EXECUTE:** For β^+ decay, the mass of the decay products must be at least two electron-masses greater than the mass of the original atom. The decay in this case is

$${}^{12}_{7}\text{N} \to {}^{12}_{6}\text{C} + \beta^+ + \nu_e.$$

The target variable is the mass M of the N-12. Using the energy released given in the problem, we have $M = m_C + 2m_e + 16.316 \text{ MeV}/c^2$. Using Table 43.2 gives

$M = 12.000000 \text{ u} + 2(0.000548580 \text{ u}) + (16.316 \text{ MeV})[\text{u}/(931.5 \text{ MeV})] = 12.018611 \text{ u}$.

EVALUATE: Check: M is greater than the mass of C-12, as it should be.

43.16. **IDENTIFY:** In each reaction the nucleon number and the total charge are conserved.

SET UP: An α particle has charge $+2e$ and nucleon number 4. An electron has charge $-e$ and nucleon number zero. A positron has charge $+e$ and nucleon number zero.

EXECUTE: **(a)** A proton changes to a neutron, so the emitted particle is a positron (β^+).

(b) The number of nucleons in the nucleus decreases by 4 and the number of protons by 2, so the emitted particle is an alpha-particle.

(c) A neutron changes to a proton, so the emitted particle is an electron (β^-).

EVALUATE: We have considered the conservation laws. We have not determined if the decays are energetically allowed.

43.17. **IDENTIFY:** Determine the energy released during tritium decay.

SET UP: In beta decay an electron, e^-, is emitted by the nucleus. The beta decay reaction is ${}^3_1\text{H} \to e^- + {}^3_2\text{He}$. If neutral atom masses are used, ${}^3_1\text{H}$ includes one electron and ${}^3_2\text{He}$ includes two electrons. One electron mass cancels and the other electron mass in ${}^3_2\text{He}$ represents the emitted electron. Or, we can subtract the electron masses and use the nuclear masses. The atomic mass of ${}^3_2\text{He}$ is 3.016029 u.

EXECUTE: **(a)** The mass of the ${}^{3}_{1}\text{H}$ nucleus is $3.016049\ \text{u} - 0.000549\ \text{u} = 3.015500\ \text{u}$. The mass of the ${}^{3}_{2}\text{He}$ nucleus is $3.016029\ \text{u} - 2(0.000549\ \text{u}) = 3.014931\ \text{u}$. The nuclear mass of ${}^{3}_{2}\text{He}$ plus the mass of the emitted electron is $3.014931\ \text{u} + 0.000549\ \text{u} = 3.015480\ \text{u}$. This is slightly less than the nuclear mass for ${}^{3}_{1}\text{H}$, so the decay is energetically allowed.

(b) The mass decrease in the decay is $3.015500\ \text{u} - 3.015480\ \text{u} = 2.0\times10^{-5}\ \text{u}$. Note that this can also be calculated as $m({}^{3}_{1}\text{H}) - m({}^{4}_{2}\text{He})$, where atomic masses are used. The energy released is $(2.0\times10^{-5}\ \text{u})(931.5\ \text{MeV/u}) = 0.019\ \text{MeV}$. The total kinetic energy of the decay products is 0.019 MeV,
or 19 keV.

EVALUATE: The energy is not shared equally by the decay products because they have unequal masses.

43.18. **IDENTIFY:** This problem involves radioactive decay and half-life.
SET UP and **EXECUTE:** The target variable is the number of decays in $0.500T_{1/2}$. We are working with the half-life of the isotope, so it is convenient to express the decay in terms of base 2 as follows:

$$N = N_0 e^{-\lambda t} = N_0 2^{-t/T_{1/2}} = N_0 2^{-(0.500T_{1/2})/T_{1/2}} = N_0 2^{-0.500}.$$

The number of decays is $\Delta N = N_0 - N = N_0 - N_0 e^{-0.500} = 0.293N_0$.
EVALUATE: Note that ΔN is *not* $N_0/4$.

43.19. **IDENTIFY** and **SET UP:** $T_{1/2} = \dfrac{\ln 2}{\lambda}$ The mass of a single nucleus is $124m_\text{p} = 2.07\times10^{-25}\ \text{kg}$.

$$|dN/dt| = 0.350\ \text{Ci} = 1.30\times10^{10}\ \text{Bq},\quad |dN/dt| = \lambda N.$$

EXECUTE: $N = \dfrac{6.13\times10^{-3}\ \text{kg}}{2.07\times10^{-25}\ \text{kg}} = 2.96\times10^{22};\ \lambda = \dfrac{|dN/dt|}{N} = \dfrac{1.30\times10^{10}\ \text{Bq}}{2.96\times10^{22}} = 4.39\times10^{-13}\ \text{s}^{-1}.$

$$T_{1/2} = \frac{\ln 2}{\lambda} = 1.58\times10^{12}\ \text{s} = 5.01\times10^{4}\ \text{y}.$$

EVALUATE: Since $T_{1/2}$ is very large, the activity changes very slowly.

43.20. **IDENTIFY:** The equation $N = N_0 e^{-\lambda t}$ can be written as $N = N_0 2^{-t/T_{1/2}}$.
SET UP: The amount of elapsed time since the source was created is roughly 2.5 years.
EXECUTE: The current activity is $N = (5000\ \text{Ci})2^{-(2.5\ \text{yr})/(5.271\ \text{yr})} = 3600\ \text{Ci}$. The source is barely usable.

EVALUATE: Alternatively, we could calculate $\lambda = \dfrac{\ln(2)}{T_{1/2}} = 0.132(\text{years})^{-1}$ and use $N = N_0 e^{-\lambda t}$ directly to obtain the same answer.

43.21. **IDENTIFY:** From the known half-life, we can find the decay constant, the rate of decay, and the activity.
SET UP: $\lambda = \dfrac{\ln 2}{T_{1/2}}$. $T_{1/2} = 4.47\times10^{9}\ \text{yr} = 1.41\times10^{17}\ \text{s}$. The activity is $\left|\dfrac{dN}{dt}\right| = \lambda N$. The mass of one ${}^{238}\text{U}$ is approximately $238m_\text{p}$. $1\ \text{Ci} = 3.70\times10^{10}\ \text{decays/s}$.

EXECUTE: **(a)** $\lambda = \dfrac{\ln 2}{1.41\times10^{17}\ \text{s}} = 4.92\times10^{-18}\ \text{s}^{-1}$.

(b) $N = \dfrac{|dN/dt|}{\lambda} = \dfrac{3.70\times10^{10}\ \text{Bq}}{4.92\times10^{-18}\ \text{s}^{-1}} = 7.52\times10^{27}$ nuclei. The mass m of uranium is the number of nuclei times the mass of each one. $m = (7.52\times10^{27})(238)(1.67\times10^{-27}\ \text{kg}) = 2.99\times10^{3}\ \text{kg}$.

(c) $N = \dfrac{10.0\times10^{-3}\text{ kg}}{238m_\text{p}} = \dfrac{10.0\times10^{-3}\text{ kg}}{238(1.67\times10^{-27}\text{ kg})} = 2.52\times10^{22}$ nuclei.

$\left|\dfrac{dN}{dt}\right| = \lambda N = (4.92\times10^{-18}\text{ s}^{-1})(2.52\times10^{22}) = 1.24\times10^{5}$ decays/s.

EVALUATE: Because ^{238}U has a very long half-life, it requires a large amount (about 3000 kg) to have an activity of a 1.0 Ci.

43.22. **IDENTIFY:** From the half-life and mass of an isotope, we can find its initial activity rate. Then using the half-life, we can find its activity rate at a later time.

SET UP: The activity $|dN/dt| = \lambda N$. $\lambda = \dfrac{\ln 2}{T_{1/2}}$. The mass of one ^{103}Pd nucleus is $103m_\text{p}$. In a time of one half-life the number of radioactive nuclei and the activity decrease by a factor of 2.

EXECUTE: **(a)** $\lambda = \dfrac{\ln 2}{T_{1/2}} = \dfrac{\ln 2}{(17\text{ days})(24\text{ h/day})(3600\text{ s/h})} = 4.7\times10^{-7}\text{ s}^{-1}$.

$N = \dfrac{0.250\times10^{-3}\text{ kg}}{103m_\text{p}} = 1.45\times10^{21}$. $|dN/dt| = (4.7\times10^{-7}\text{ s}^{-1})(1.45\times10^{21}) = 6.8\times10^{14}$ Bq.

(b) 68 days is $4T_{1/2}$ so the activity is $(6.8\times10^{14}\text{ Bq})/2^4 = 4.2\times10^{13}$ Bq.

EVALUATE: At the end of 4 half-lives, the activity rate is less than a tenth of its initial rate.

43.23. **IDENTIFY** and **SET UP:** As discussed in Section 43.4, the activity $A = |dN/dt|$ obeys the same decay equation as $N(t)$: $A = A_0 e^{-\lambda t}$. For ^{14}C, $T_{1/2} = 5730$ y and $\lambda = \ln 2/T_{1/2}$ so $A = A_0 e^{-(\ln 2)t/T_{1/2}}$; calculate A at each t; $A_0 = 184$ decays/min.

EXECUTE: **(a)** For t = 1000 y, we have A = (184 decays/min)$e^{-(\ln 2)(1000\text{ y})/(5730\text{ y})}$ = 163 decays/min.
(b) For t = 50,000 y, the same equation gives A = 0.435 decays/min.
EVALUATE: The time in part (b) is 8.73 half-lives, so the decay rate has decreased by a factor of $(\frac{1}{2})^{8.73}$.

43.24. **IDENTIFY** and **SET UP:** The decay rate decreases by a factor of 2 in a time of one half-life.

EXECUTE: **(a)** 24 days is 3 half-lives, so the activity at the end of that time is $(325\text{ Bq})/(2^3) = 40.6$ Bq, which rounds to 41 Bq.
(b) The activity is proportional to the number of radioactive nuclei, so the percent is

$$\frac{17.0\text{ Bq}}{40.6\text{ Bq}} = 0.42 = 42\%.$$

(c) ${}^{131}_{53}\text{I} \to {}^{0}_{-1}\text{e} + {}^{131}_{54}\text{Xe}$. The nucleus ${}^{131}_{54}\text{Xe}$ is produced.

EVALUATE: Both the activity and the number of radioactive nuclei present decrease by a factor of 2 in one half-life.

43.25. **IDENTIFY:** This problem is about radioactive decay.

SET UP: We are working with the half-life of the isotope, so it is convenient to express the decay in terms of base 2 when needed. $N = N_0 e^{-\lambda t} = N_0 2^{-t/T_{1/2}}$

EXECUTE: **(a)** We want to know the number of nuclei initially present. We know the initial rate of decay, which is dN/dt, so

$$dN/dt = d(N_0 e^{-\lambda t})/dt = -\lambda N_0 e^{-\lambda t}.$$

At t = 0, $dN/dt = -8.0\times10^{16}$ Bq. Solving for N_0 gives

$N_0 = \dfrac{1}{\lambda}\dfrac{dN}{dt} = -\dfrac{T_{1/2}}{0.693}\dfrac{dN}{dt} = -\dfrac{(64.0)(3600\text{ s})}{0.693}\left(-8.0\times10^{16}\text{ Bq}\right) = 2.7\times10^{22}$ nuclei.

(b) We want the number of nuclei remaining at the end of 12.0 days. Use base 2 for simplicity.

$$N = N_0 2^{-t/T_{1/2}} = (2.66\times10^{22})2^{-(12.0)(24.\text{h})(64.0\text{h})} = 1.2\times10^{21}\text{nuclei.}$$

EVALUATE: Note that 12.0 days is 4.5 half-lives, so $N/N_0 = 2^{-4.5}$.

43.26. IDENTIFY: Apply $|dN/dt| = \lambda N$ to calculate N, the number of radioactive nuclei originally present in the spill. Since the activity A is proportional to the number of radioactive nuclei, $N = N_0 e^{-\lambda t}$ leads to $A = A_0 e^{-\lambda t}$, where A is the activity.

SET UP: The mass of one ^{131}Ba nucleus is about 131 u.

EXECUTE: **(a)** $\left|\dfrac{dN}{dt}\right| = 400\ \mu\text{Ci} = (400\times10^{-6})(3.70\times10^{10}\ \text{s}^{-1}) = 1.48\times10^{7}$ decays/s.

$$T_{1/2} = \frac{\ln 2}{\lambda} \to \lambda = \frac{\ln 2}{T_{1/2}} = \frac{\ln 2}{(12\text{ d})(86{,}400\text{ s/d})} = 6.69\times10^{-7}\ \text{s}^{-1}.$$

$\left|\dfrac{dN}{dt}\right| = \lambda N \Rightarrow N = \dfrac{|dN/dt|}{\lambda} = \dfrac{1.48\times10^{7}\ \text{decays/s}}{6.69\times10^{-7}\text{s}^{-1}} = 2.21\times10^{13}\text{nuclei.}$ The mass of these ^{131}Ba nuclei is

$$m = (2.21\times10^{13}\ \text{nuclei})\times(131\times1.66\times10^{-27}\ \text{kg/nucleus}) = 4.8\times10^{-12}\ \text{kg} = 4.8\times10^{-9}\ \text{g} = 4.8\ \text{ng}.$$

(b) $A = A_0 e^{-\lambda t}$. $1\ \mu\text{Ci} = (400\ \mu\text{Ci})\, e^{-\lambda t}$. $\ln(1/400) = -\lambda t$.

$$t = -\frac{\ln(1/400)}{\lambda} = -\frac{\ln(1/400)}{6.69\times10^{-7}\text{s}^{-1}} = 8.96\times10^{6}\ \text{s}\left(\frac{1\ \text{d}}{86{,}400\ \text{s}}\right) = 104\ \text{days}.$$

EVALUATE: The time is about 8.7 half-lives and the activity after that time is $(400\ \mu\text{Ci})\left(\tfrac{1}{2}\right)^{8.7} \approx 1\mu\text{Ci}$.

43.27. IDENTIFY: Apply $A = A_0 e^{-\lambda t}$ and $\lambda = \ln 2/T_{1/2}$.

SET UP: $\ln e^{x} = x$.

EXECUTE: $A = A_0 e^{-\lambda t} = A_0 e^{-t(\ln 2)/T_{1/2}}$. $-\dfrac{(\ln 2)t}{T_{1/2}} = \ln(A/A_0)$.

$$T_{1/2} = -\frac{(\ln 2)t}{\ln(A/A_0)} = -\frac{(\ln 2)(4.00\ \text{days})}{\ln(3091/8318)} = 2.80\ \text{days}.$$

EVALUATE: The activity has decreased by more than half and the elapsed time is more than one half-life.

43.28. IDENTIFY: Apply $A = A_0 e^{-\lambda t}$.

SET UP: From Example 43.9, $\lambda = 3.83\times10^{-12}\ \text{s}^{-1} = 1.21\times10^{-4}\ \text{y}^{-1}$ for radiocarbon.

EXECUTE: The activity of the sample is $\dfrac{2690\ \text{decays/min}}{(60\ \text{s/min})(0.500\ \text{kg})} = 89.7\ \text{Bq/kg}$, while the activity of atmospheric carbon is $255\ \text{Bq/kg}$ (see Example 43.9). The age of the sample is then

$$t = -\frac{\ln(89.7/225)}{\lambda} = -\frac{\ln(89.7/225)}{1.21\times10^{-4}/\text{y}} = 8640\ \text{y}.$$

EVALUATE: For ^{14}C, $T_{1/2} = 5730\ \text{y}$. The age is more than one half-life and the activity per kg of carbon is less than half the value when the tree died.

43.29. IDENTIFY and SET UP: Apply $|dN/dt| = \lambda N$ with $\lambda = \ln 2/T_{1/2}$. In one half-life, one half of the nuclei decay.

EXECUTE: **(a)** $\left|\dfrac{dN}{dt}\right| = 7.56\times10^{11}\ \text{Bq} = 7.56\times10^{11}$ decays/s.

$$\lambda = \frac{0.693}{T_{1/2}} = \frac{0.693}{(30.8 \text{ min})(60 \text{ s/min})} = 3.75\times10^{-4} \text{ s}^{-1}.$$

$$N_0 = \frac{1}{\lambda}\left|\frac{dN}{dt}\right| = \frac{7.56\times10^{11} \text{ decay/s}}{3.75\times10^{-4} \text{ s}^{-1}} = 2.02\times10^{15} \text{ nuclei.}$$

(b) The number of nuclei left after one half-life is $\frac{N_0}{2} = 1.01\times10^{15}$ nuclei, and the activity is half: $\left|\frac{dN}{dt}\right| = 3.78\times10^{11}$ decays/s.

(c) After three half-lives (92.4 minutes) there is an eighth of the original amount, so $N = 2.53\times10^{14}$ nuclei, and an eighth of the activity: $\left|\frac{dN}{dt}\right| = 9.45\times10^{10}$ decays/s.

EVALUATE: Since the activity is proportional to the number of radioactive nuclei that are present, the activity is halved in one half-life.

43.30. IDENTIFY and SET UP: $1 \text{ Gy} = 1 \text{ J/kg}$ and is the SI unit of absorbed dose. $1 \text{ rad} = 0.010 \text{ Gy}$. Sv is the SI unit for equivalent dose. Equivalent dose $=$ RBE $\times$ absorbed dose. Rem is the equivalent dose when the absorbed dose is in rad. For x rays, $\text{RBE} = 1.0$. For protons, $\text{RBE} = 10$.

EXECUTE: **(a)** 5.0 Gy, 500 rad. $\text{RBE} = 1.0$, so equivalent dose $=$ absorbed dose. 5.0 Sv and 500 rem.

(b) $(70.0 \text{ kg})(5.0 \text{ J/kg}) = 350 \text{ J}$.

(c) The absorbed dose and total absorbed energy are the same but the equivalent dose is 10 times larger. So the answers are: 5.0 Gy, 500 rad, 50 Sv, 5000 rem, 350 J.

EVALUATE: The same energy deposited by protons as x rays is ten times greater in its biological effect.

43.31. IDENTIFY and SET UP: The unit for absorbed dose is $1 \text{ rad} = 0.01 \text{ J/kg} = 0.01 \text{ Gy}$. Equivalent dose in rem is RBE times absorbed dose in rad.

EXECUTE: $1 \text{ rad} = 10^{-2} \text{ Gy}$, so $1 \text{ Gy} = 100 \text{ rad}$ and the dose was 500 rad.

$\text{rem} = (\text{rad})(\text{RBE}) = (500 \text{ rad})(4.0) = 2000 \text{ rem}$. $1 \text{ Gy} = 1 \text{ J/kg}$, so 5.0 J/kg.

EVALUATE: Gy, rad, and J/kg are all units of absorbed dose. Rem is a unit of equivalent dose, which depends on the RBE of the radiation.

43.32. IDENTIFY and SET UP: The unit for absorbed dose is $1 \text{ rad} = 0.01 \text{ J/kg} = 0.01 \text{ Gy}$. Equivalent dose in rem is RBE times absorbed dose in rad.

EXECUTE: **(a)** $\text{rem} = \text{rad}\times\text{RBE}$. $300 = x(10)$ and $x = 30$ rad.

(b) 1 rad deposits 0.010 J/kg, so 30 rad deposit 0.30 J/kg. This radiation affects 25 g (0.025 kg) of tissue, so the total energy is $(0.025 \text{ kg})(0.30 \text{ J/kg}) = 7.5\times10^{-3} \text{ J} = 7.5 \text{ mJ}$.

(c) $\text{RBE} = 1$ for β-rays, so rem $=$ rad. Therefore 30 rad $=$ 30 rem.

EVALUATE: The same absorbed dose produces a larger equivalent dose when the radiation is neutrons than when it is electrons.

43.33. IDENTIFY and SET UP: For x rays $\text{RBE} = 1$ and the equivalent dose equals the absorbed dose.

EXECUTE: **(a)** 175 krad $=$ 175 krem $=$ 1.75 kGy $=$ 1.75 kSv. $(1.75\times10^3 \text{ J/kg})(0.220 \text{ kg}) = 385 \text{ J}$.

(b) 175 krad $=$ 1.75 kGy; $(1.50)(175 \text{ krad}) = 262.5 \text{ krem} = 2.625 \text{ kSv}$. The energy deposited would be 385 J, the same as in (a).

EVALUATE: The energy required to raise the temperature of 0.220 kg of water 1 C° is 922 J, and 385 J is less than this. The energy deposited corresponds to a very small amount of heating.

43.34. IDENTIFY and SET UP: For x rays $\text{RBE} = 1$ so the equivalent dose in Sv is the same as the absorbed dose in J/kg.

EXECUTE: One whole-body scan delivers $(75\text{ kg})(12\times10^{-3}\text{ J/kg}) = 0.90\text{ J}$. One chest x ray delivers $(5.0\text{ kg})(0.20\times10^{-3}\text{ J/kg}) = 1.0\times10^{-3}\text{ J}$. It takes $\dfrac{0.90\text{ J}}{1.0\times10^{-3}\text{ J}} = 900$ chest x rays to deliver the same total energy.

EVALUATE: For the CT scan the equivalent dose is much larger, and it is applied to the whole body.

43.35. **IDENTIFY:** This problem looks at the biological effects of radiation.

SET UP: $N = N_0e^{-\lambda t}$, $\lambda = 0.693/T_{½} = 0.693/(29\text{ y}) = 0.0239\text{ y}^{-1}$.

EXECUTE: **(a)** We want the absorbed dose during one year from 1.0 μg of Sr-90. First find the number of decays ΔN that occur during one year. Each decay releases 1.1 MeV of energy. The mass of a Sr-90 atom is approximately $38m_p + 52m_n + 38m_e = 1.5067 \times 10^{-25}$ kg. If N_0 is the number of Sr-90 atoms in the 1.0-μg sample, then $(1.5067 \times 10^{-25}\text{ kg})N_0 = 1.0\ \mu\text{g}$, which gives $N_0 = 6.637 \times 10^{15}$ atoms. At the end of one year, the number of atoms N that are left will be $N = N_0e^{-\lambda(1\text{ y})}$. The number of decays during the year is $N_0 - N = N_0 - N_0e^{-\lambda(1\text{ y})} = (6.637 \times 10^{15})[1 - e^{-(0.0239/\text{y})(1\text{ y})}] = 1.567 \times 10^{14}$ decays. The total energy E absorbed by these decays is $E = (1.567 \times 10^{14})(1.1\text{ MeV}) = 27.59$ J. This energy is delivered to 50 kg of body tissue, so the absorbed dose is (27.59 J)/(50 kg) = 0.55 J/kg = 0.55 Gy. Since 1 rad = 0.01 Gy, this dose is also 55 rad.

(b) We want the equivalent dose. Equivalent dose (in Sv) = RBE $\times$ absorbed dose (in Gy). From Table 43.3, the RBE for gamma rays is 1, and the RBE for electrons is given in the problem as 1.0. So the maximum equivalent dose is (1.0)(0.55 Gy) = 0.55 Sv. Since 1 rem = 0.01 Sv, we can also say that the equivalent dose is 55 rem.

EVALUATE: The longer the exposure lasts, the greater the dose because more decays take place.

43.36. **IDENTIFY:** 1 rem = 0.01 Sv. Equivalent dose in rem equals RBE times the absorbed dose in rad. 1 rad = 0.01 J/kg. To change the temperature of water, $Q = mc\Delta T$.

SET UP: For water, $c = 4190\text{ J/kg}\cdot\text{K}$.

EXECUTE: **(a)** $5.4\text{ Sv}(100\text{ rem/Sv}) = 540\text{ rem}$.

(b) The RBE of 1 gives an absorbed dose of 540 rad.

(c) The absorbed dose is 5.4 Gy, so the total energy absorbed is $(5.4\text{ Gy})(65\text{ kg}) = 351\text{ J}$. The energy required to raise the temperature of 65 kg by 0.010° C is $(65\text{ kg})(4190\text{ J/kg}\cdot\text{K})(0.01\text{ C°}) = 3\text{ kJ}$.

EVALUATE: The amount of energy received corresponds to a very small heating of his body.

43.37. **IDENTIFY:** Each photon delivers energy. The energy of a single photon depends on its wavelength.

SET UP: equivalent dose (rem) = RBE$\times$absorbed dose (rad). 1 rad = 0.010 J/kg. For x rays, RBE = 1. Each photon has energy $E = \dfrac{hc}{\lambda}$.

EXECUTE: **(a)** $E = \dfrac{hc}{\lambda} = \dfrac{(6.63\times10^{-34}\text{ J}\cdot\text{s})(3.00\times10^{8}\text{ m/s})}{0.0200\times10^{-9}\text{ m}} = 9.94\times10^{-15}\text{ J}$. The absorbed energy is

$$(5.00\times10^{10}\text{ photons})(9.94\times10^{-15}\text{ J/photon}) = 4.97\times10^{-4}\text{ J} = 0.497\text{ mJ}.$$

(b) The absorbed dose is $\dfrac{4.97\times10^{-4}\text{ J}}{0.600\text{ kg}} = 8.28\times10^{-4}\text{ J/kg} = 0.0828\text{ rad}$. Since RBE = 1, the equivalent dose is 0.0828 rem.

EVALUATE: The amount of energy absorbed is rather small (only $\frac{1}{2}$ mJ), but it is absorbed by only 600 g of tissue.

43.38. **IDENTIFY:** The reaction energy Q is $Q = (M_A + M_B - M_C - M_D)c^2$.

SET UP: $Q = (m_{\text{H-1}} + m_{\text{H-3}} - m_{\text{H-2}} - m_{\text{H-2}})c^2$. Use the masses in Table 43.2 and $m_n = 1.008665$ u for the neutron. The masses in Table 43.2 are for neutral atoms and therefore include the mass of the electrons. 1 u is equivalent to 931.5 MeV.

EXECUTE: $Q = [1.007825\text{ u} + 3.016049\text{ u} - 2(2.014102\text{ u})](931.5\text{ MeV/u}) = -4.033\text{ MeV}$.

EVALUATE: Since Q is negative, the initial energy is less than the final energy, so energy had to be put into the system to cause the reaction to occur. Therefore, this is an endoergic reaction.

43.39. **(a) IDENTIFY** and **SET UP:** Determine X by balancing the charge and the nucleon number on the two sides of the reaction equation.

EXECUTE: X must have $A = +2 + 9 - 4 = 7$ and $Z = +1 + 4 - 2 = 3$. Thus X is ${}^7_3\text{Li}$ and the reaction is ${}^2_1\text{H} + {}^9_4\text{Be} = {}^7_3\text{Li} + {}^4_2\text{He}$.

(b) IDENTIFY and **SET UP:** Calculate the mass decrease and find its energy equivalent.

EXECUTE: If we use the neutral atom masses then there are the same number of electrons (five) in the reactants as in the products. Their masses cancel, so we get the same mass defect whether we use nuclear masses or neutral atom masses. The neutral atoms masses are given in Table 43.2. 1 u is equivalent to 931.5 MeV.

$${}^2_1\text{H} + {}^9_4\text{Be} \text{ has mass } 2.014102\text{ u} + 9.012182\text{ u} = 11.26284\text{ u}.$$

$${}^7_3\text{Li} + {}^4_2\text{He} \text{ has mass } 7.016005\text{ u} + 4.002603\text{ u} = 11.018608\text{ u}.$$

The mass decrease is $11.026284\text{ u} - 11.018608\text{ u} = 0.007676\text{ u}$.

This corresponds to an energy release of $(0.007676\text{ u})(931.5\text{ MeV/1 u}) = 7.150\text{ MeV}$.

(c) IDENTIFY and **SET UP:** Estimate the threshold energy by calculating the Coulomb potential energy when the ${}^2_1\text{H}$ and ${}^9_4\text{Be}$ nuclei just touch. Obtain the nuclear radii from $R = R_0 A^{1/3}$.

EXECUTE: The radius R_{Be} of the ${}^9_4\text{Be}$ nucleus is $R_{\text{Be}} = (1.2\times10^{-15}\text{ m})(9)^{1/3} = 2.5\times10^{-15}\text{ m}$.

The radius R_{H} of the ${}^2_1\text{H}$ nucleus is $R_{\text{H}} = (1.2\times10^{-15}\text{ m})(2)^{1/3} = 1.5\times10^{-15}\text{ m}$.

The nuclei touch when their center-to-center separation is

$R = R_{\text{Be}} + R_{\text{H}} = 4.0\times10^{-15}\text{ m}$.

The Coulomb potential energy of the two reactant nuclei at this separation is

$$U = \frac{1}{4\pi\epsilon_0}\frac{q_1 q_2}{r} = \frac{1}{4\pi\epsilon_0}\frac{e(4e)}{r}.$$

$$U = (8.988\times10^9\text{ N}\cdot\text{m}^2/\text{C}^2)\frac{4(1.602\times10^{-19}\text{ C})^2}{(4.0\times10^{-15}\text{ m})(1.602\times10^{-19}\text{ J/eV})} = 1.4\text{ MeV}.$$

This is an estimate of the threshold energy for this reaction.

EVALUATE: The reaction releases energy but the total initial kinetic energy of the reactants must be 1.4 MeV in order for the reacting nuclei to get close enough to each other for the reaction to occur. The nuclear force is strong but is very short-range.

43.40. **IDENTIFY:** The energy released is the energy equivalent of the mass decrease that occurs in the reaction.

SET UP: 1 u is equivalent to 931.5 MeV.

EXECUTE: $m_{{}^3_2\text{He}} + m_{{}^2_1\text{H}} - m_{{}^4_2\text{He}} - m_{{}^1_1\text{H}} = 1.97\times10^{-2}\text{ u}$, so the energy released is 18.4 MeV.

EVALUATE: Using neutral atom masses includes three electron masses on each side of the reaction equation and the same result is obtained as if nuclear masses had been used.

43.41. **IDENTIFY** and **SET UP:** The energy released is the energy equivalent of the mass decrease. 1 u is equivalent to 931.5 MeV. The mass of one ${}^{235}\text{U}$ nucleus is $235m_{\text{p}}$.

EXECUTE: **(a)** ${}^{235}_{92}\text{U} + {}^1_0\text{n} \to {}^{144}_{56}\text{Ba} + {}^{89}_{36}\text{Kr} + 3{}^1_0\text{n}$. We can use atomic masses since the same number of electrons are included on each side of the reaction equation and the electron masses cancel. The mass decrease is $\Delta M = m({}^{235}_{92}\text{U}) + m({}^1_0\text{n}) - [m({}^{144}_{56}\text{Ba}) + m({}^{89}_{36}\text{Kr}) + 3m({}^1_0\text{n})]$,

$\Delta M = 235.043930\text{ u} + 1.0086649\text{ u} - 143.922953\text{ u} - 88.917631\text{ u} - 3(1.0086649\text{ u}),\quad \Delta M = 0.1860\text{ u}.$ The energy released is $(0.1860\text{ u})(931.5\text{ MeV/u}) = 173.3\text{ MeV}$.

(b) The number of ^{235}U nuclei in 1.00 g is $\dfrac{1.00\times10^{-3}\text{ kg}}{235m_\text{p}} = 2.55\times10^{21}$. The energy released per gram is $(173.3\text{ MeV/nucleus})(2.55\times10^{21}\text{ nuclei/g}) = 4.42\times10^{23}\text{ MeV/g}$.

EVALUATE: The energy released is 7.1×10^{10} J/kg. This is much larger than typical heats of combustion, which are about 5×10^4 J/kg.

43.42. **IDENTIFY:** The charge and the nucleon number are conserved. The energy of the photon must be at least as large as the energy equivalent of the mass increase in the reaction.
SET UP: 1 u is equivalent to 931.5 MeV.
EXECUTE: **(a)** $^{28}_{14}\text{Si} + \gamma \Rightarrow ^{24}_{12}\text{Mg} + ^{A}_{Z}\text{X}$. $A + 24 = 28$ so $A = 4$. $Z + 12 = 14$ so $Z = 2$. X is an α particle.
(b) $-\Delta m = m(^{24}_{12}\text{Mg}) + m(^{4}_{2}\text{He}) - m(^{28}_{14}\text{Si}) = 23.985042\text{ u} + 4.002603\text{ u} - 27.976927\text{ u} = 0.010718\text{ u}$.
$E_\gamma = (-\Delta m)c^2 = (0.010718\text{ u})(931.5\text{ MeV/u}) = 9.984\text{ MeV}$.
EVALUATE: The wavelength of the photon is
$\lambda = \dfrac{hc}{E} = \dfrac{(4.136\times10^{-15}\text{ eV}\cdot\text{s})(3.00\times10^{8}\text{ m/s})}{9.984\times10^{6}\text{ eV}} = 1.24\times10^{-13}\text{ m} = 1.24\times10^{-4}\text{ nm}$. This is a gamma ray photon.

43.43. **IDENTIFY:** Charge and the number of nucleons are conserved in the reaction. The energy absorbed or released is determined by the mass change in the reaction.
SET UP: 1 u is equivalent to 931.5 MeV.
EXECUTE: **(a)** $Z = 3 + 2 - 0 = 5$ and $A = 4 + 7 - 1 = 10$.
(b) The nuclide is a boron nucleus, and z and so 2.79 MeV of energy is absorbed.
EVALUATE: The absorbed energy must come from the initial kinetic energy of the reactants.

43.44. **IDENTIFY:** We are looking at the energy released during radioactive decay.
SET UP: The decay is $^{10}_{4}\text{Be} \to ^{10}_{5}\text{B} + \beta + \bar{\nu}_\text{e}$.
EXECUTE: **(a)** The target variable is the released energy. Beta-minus decay can occur only if the mass of the original atom is greater than the mass of the final atom, which in this case is true. Use Table 43.2.
$\Delta m = m_\text{i} - m_\text{f} = 10.013535\text{ u} - 10.012937 = 0.000598\text{ u}$. The energy E released is

$$E = (0.000598\text{ u})[(931.5\text{ MeV})/\text{u}] = 0.557\text{ MeV}.$$

(b) We want the speed of the beta-minus particle. The released energy is a bit larger than the rest energy of the electron (0.511 MeV), so we need to use relativity. First find γ and then use it to find v.

$$E = K = mc^2(\gamma - 1)$$

$$\gamma = \frac{K}{mc^2} + 1 = \frac{0.577\text{ MeV}}{0.511\text{ MeV}} + 1 = 2.09$$

$$v = c\sqrt{1 - 1/\gamma^2} = c\sqrt{1 - 1/(2.09)^2} = 0.87c.$$

EVALUATE: Special relativity definitely cannot be neglected at such a high speed.

43.45. **IDENTIFY** and **SET UP:** $m = \rho V$. $1\text{ gal} = 3.788\text{ L} = 3.788\times10^{-3}\text{ m}^3$. The mass of a ^{235}U nucleus is $235m_\text{p}$. $1\text{ MeV} = 1.60\times10^{-13}$ J.

EXECUTE: **(a)** For 1 gallon, $m = \rho V = (737\text{ kg/m}^3)(3.788\times10^{-3}\text{ m}^3) = 2.79\text{ kg} = 2.79\times10^3$ g.

$$\frac{1.3\times10^{8}\text{ J/gal}}{2.79\times10^{3}\text{ g/gal}} = 4.7\times10^{4}\text{ J/g}.$$

(b) 1 g contains $\dfrac{1.00\times10^{-3}\text{ kg}}{235m_\text{p}} = 2.55\times10^{21}$ nuclei.

$$(200\text{ MeV/nucleus})(1.60\times10^{-13}\text{ J/MeV})(2.55\times10^{21}\text{ nuclei}) = 8.2\times10^{10}\text{ J/g}.$$

(c) A mass of $6m_\text{p}$ produces 26.7 MeV.

$$\frac{(26.7\text{ MeV})(1.60\times10^{-13}\text{ J/MeV})}{6m_\text{p}} = 4.26\times10^{14}\text{ J/kg} = 4.26\times10^{11}\text{ J/g}.$$

(d) The total energy available would be $(1.99\times10^{30}\text{ kg})(4.7\times10^{7}\text{ J/kg}) = 9.4\times10^{37}\text{ J}$.

$$\text{Power} = \frac{\text{energy}}{t} \text{ so } t = \frac{\text{energy}}{\text{power}} = \frac{9.4\times10^{37}\text{ J}}{3.86\times10^{26}\text{ W}} = 2.4\times10^{11}\text{ s} = 7600\text{ y}.$$

EVALUATE: If the mass of the sun were all proton fuel, it would contain enough fuel to last

$$(7600\text{ y})\left(\frac{4.3\times10^{11}\text{ J/g}}{4.7\times10^{4}\text{ J/g}}\right) = 7.0\times10^{10}\text{ y}.$$

43.46. **IDENTIFY:** The minimum energy to remove a proton from the nucleus is equal to the energy difference between the two states of the nucleus (before and after proton removal).

(a) SET UP: ${}^{12}_{6}\text{C} = {}^{1}_{1}\text{H} + {}^{11}_{5}\text{B}$. $\Delta m = m({}^{1}_{1}\text{H}) + m({}^{11}_{5}\text{B}) - m({}^{12}_{6}\text{C})$. The electron masses cancel when neutral atom masses are used.

EXECUTE: $\Delta m = 1.007825\text{ u} + 11.009305\text{ u} - 12.000000\text{ u} = 0.01713\text{ u}$. The energy equivalent of this mass increase is $(0.01713\text{ u})(931.5\text{ MeV/u}) = 16.0\text{ MeV}$.

(b) SET UP and **EXECUTE:** We follow the same procedure as in part (a).

$\Delta M = 6M_\text{H} + 6M_\text{n} - {}^{12}_{6}M = 6(1.007825\text{ u}) + 6(1.008665\text{ u}) - 12.000000\text{ u} = 0.09894\text{ u}$.

$$E_\text{B} = (0.09894\text{ u})(931.5\text{ MeV/u}) = 92.16\text{ MeV}. \quad \frac{E_\text{B}}{A} = 7.68\text{ MeV/u}.$$

EVALUATE: The proton removal energy is about twice the binding energy per nucleon.

43.47. **IDENTIFY:** The minimum energy to remove a proton or a neutron from the nucleus is equal to the energy difference between the two states of the nucleus, before and after removal.

(a) SET UP: ${}^{17}_{8}\text{O} = {}^{1}_{0}\text{n} + {}^{16}_{8}\text{O}$. $\Delta m = m({}^{1}_{0}\text{n}) + m({}^{16}_{8}\text{O}) - m({}^{17}_{8}\text{O})$. The electron masses cancel when neutral atom masses are used.

EXECUTE: $\Delta m = 1.008665\text{ u} + 15.994915\text{ u} - 16.999132\text{ u} = 0.004448\text{ u}$. The energy equivalent of this mass increase is $(0.004448\text{ u})(931.5\text{ MeV/u}) = 4.14\text{ MeV}$.

(b) SET UP and **EXECUTE:** Following the same procedure as in part (a) gives

$\Delta M = 8M_\text{H} + 9M_\text{n} - {}^{17}_{8}M = 8(1.007825\text{ u}) + 9(1.008665\text{ u}) - 16.999132\text{ u} = 0.1415\text{ u}$.

$$E_\text{B} = (0.1415\text{ u})(931.5\text{ MeV/u}) = 131.8\text{ MeV}. \quad \frac{E_\text{B}}{A} = 7.75\text{ MeV/nucleon}.$$

EVALUATE: The neutron removal energy is about half the binding energy per nucleon.

43.48. **IDENTIFY:** This problem is about the heat released by radioactive decay.

SET UP and **EXECUTE:** **(a)** We want the number of U-238 atoms in 1 kg of mantle material. The mass of U-238 is about $238m_\text{P} = 3.975\times10^{-25}$ kg. If N is the number of U-238 atoms in 31 μg of material, then $(3.975\times10^{-25}\text{ kg})N = 31\times10^{-9}$ kg. So $N = 7.800\times10^{16}$ atoms of U-238 in 31 μg of U-238 which is also the number of U-238 atoms in 1 kg of mantle material.

(b) We want the decay constant. $\lambda = 0.693/T_{1/2}$. $T_{1/2} = 4.47\times10^{9}\text{ y} = 1.4\times10^{17}$ s. Using this gives $\lambda = 4.9\times10^{-18}\text{ s}^{-1}$.

(c) Multiplying our results as directed gives $\lambda N = 0.38$ decays/s·kg.

(d) Converting units gives

$$\left(0.38\frac{\text{decays/s}}{\text{kg}}\right)(52\ \text{MeV/decay})\left(1.60\times10^{-13}\ \text{J/MeV}\right)=3.2\times10^{-12}\ \text{W/kg}.$$

(e) We want the power. Using the result from part (d) and the information in the problem gives

$$P=\left(3.2\times10^{-12}\ \text{W/kg}\right)\left[\frac{2}{3}\left(6\times10^{24}\ \text{kg}\right)\right]=1.3\times10^{13}\ \text{W}\approx10\ \text{TW}.$$

(f) Use the power from part (e). $0.39E_{\text{tot}}$ = 13 TW, so E_{tot} = 30 TW.

(g) We want the total power. $P_{\text{tot}} - P_{\text{out}} = P_{\text{net}}$, so $P_{\text{tot}} = P_{\text{net}} + P_{\text{out}} = P_{\text{rad}} + P_{\text{rad}} = 2P_{\text{rad}}$ = 60 TW.

EVALUATE: The power from radioactivity comes largely from the mantle and the power from left over heat comes largely from the hot cores.

43.49. IDENTIFY: Use the decay scheme and half-life of ^{90}Sr to find out the product of its decay and the amount left after a given time.

SET UP: The particle emitted in β^- decay is an electron, ${}^{0}_{-1}\text{e}$. In a time of one half-life, the number of radioactive nuclei decreases by a factor of 2. $6.25\% = \dfrac{1}{16} = 2^{-4}$.

EXECUTE: **(a)** ${}^{90}_{38}\text{Sr} \to {}^{0}_{-1}\text{e} + {}^{90}_{39}\text{Y}$. The daughter nucleus is ${}^{90}_{39}\text{Y}$.

(b) 56 y is $2T_{1/2}$ so $N = N_0/2^2 = N_0/4$; 25% is left.

(c) $\dfrac{N}{N_0} = 2^{-n}$; $\dfrac{N}{N_0} = 6.25\% = \dfrac{1}{16} = 2^{-4}$, so $t = 4T_{1/2} = 112$ y.

EVALUATE: After half a century, $\frac{1}{4}$ of the ^{90}Sr would still be left!

43.50. IDENTIFY: Calculate the mass defect for the decay. Example 43.5 uses conservation of linear momentum to determine how the released energy is divided between the decay partners.

SET UP: 1 u is equivalent to 931.5 MeV.

EXECUTE: The α-particle will have $\dfrac{226}{230}$ of the released energy (see Example 43.5).

$$\frac{226}{230}(m_{\text{Th}} - m_{\text{Ra}} - m_{\text{He-4}}) = 5.032\times10^{-3}\ \text{u or 4.69 MeV}.$$

EVALUATE: Most of the released energy goes to the α particle, since its mass is much less than that of the daughter nucleus.

43.51. (a) IDENTIFY and **SET UP:** The heavier nucleus will decay into the lighter one.

EXECUTE: ${}^{25}_{13}\text{Al}$ will decay into ${}^{25}_{12}\text{Mg}$.

(b) IDENTIFY and **SET UP:** Determine the emitted particle by balancing A and Z in the decay reaction.

EXECUTE: This gives ${}^{25}_{13}\text{Al} \to {}^{25}_{12}\text{Mg} + {}^{0}_{+1}\text{e}$. The emitted particle must have charge $+e$ and its nucleon number must be zero. Therefore, it is a β^+ particle, a positron.

(c) IDENTIFY and **SET UP:** Calculate the energy defect ΔM for the reaction and find the energy equivalent of ΔM. Use the nuclear masses for ${}^{25}_{13}\text{Al}$ and ${}^{25}_{12}\text{Mg}$, to avoid confusion in including the correct number of electrons if neutral atom masses are used.

EXECUTE: The nuclear mass for ${}^{25}_{13}\text{Al}$ is

$M_{\text{nuc}}({}^{25}_{13}\text{Al}) = 24.990428\ \text{u} - 13(0.000548580\ \text{u}) = 24.983296\ \text{u}.$

The nuclear mass for ${}^{25}_{12}\text{Mg}$ is $M_{\text{nuc}}({}^{25}_{12}\text{Mg}) = 24.985837\ \text{u} - 12(0.000548580\ \text{u}) = 24.979254\ \text{u}.$

The mass defect for the reaction is

$\Delta M = M_{\text{nuc}}({}^{25}_{13}\text{Al}) - M_{\text{nuc}}({}^{25}_{12}\text{Mg}) - M({}^{0}_{+1}\text{e}) = 24.983296\ \text{u} - 24.979254\ \text{u} - 0.00054858\ \text{u} = 0.003493\ \text{u}.$

$$Q = (\Delta M)c^2 = 0.003493\ \text{u}(931.5\ \text{MeV/1 u}) = 3.254\ \text{MeV}.$$

EVALUATE: The mass decreases in the decay and energy is released. Note: ${}^{25}_{13}\text{Al}$ can also decay into ${}^{25}_{12}\text{Mg}$ by the electron capture: ${}^{25}_{13}\text{Al} + {}^{0}_{-1}\text{e} \to {}^{25}_{12}\text{Mg}$. The ${}^{0}_{-1}$ electron in the reaction is an orbital electron in the neutral ${}^{25}_{13}\text{Al}$ atom. The mass defect can be calculated using the nuclear masses:

$\Delta M = M_{\text{nuc}}({}^{25}_{13}\text{Al}) + M({}^{0}_{-1}\text{e}) - M_{\text{nuc}}({}^{25}_{12}\text{Mg}) = 24.983296\ \text{u} + 0.00054858\ \text{u} - 24.979254\ \text{u} = 0.004591\ \text{u}.$

$Q = (\Delta M)c^2 = (0.004591\ \text{u})(931.5\ \text{MeV/1 u}) = 4.277\ \text{MeV}.$ The mass decreases in the decay and energy is released.

43.52. **IDENTIFY:** This problem is about nuclear fusion reactions in the sun.

SET UP and **EXECUTE:** Follow the directions for each part. **(a)** We want the number N of fusion reactions per second. One alpha particle is produced for each cycle of the proton-proton chain, and each cycle produces 27.73 MeV. Using the given power, we have

$$(26.73\ \text{MeV/cycle})\left(1.60\times10^{-13}\ \text{J/MeV}\right)N = 3.8\times10^{26}\ \text{W}$$

$N = 8.885 \times 10^{37}$ reactions/s, which rounds to $N = 8.9 \times 10^{37}$ reactions/s.

(b) Each cycle produces 2 neutrinos, so $N_\nu = 1.8 \times 10^{38}$ neutrinos/s.

(c) We want the number of neutrinos that hit the earth per second. Assume that the neutrinos travel outward uniformly in all directions. Call N_E the number that hit the earth, r the earth-sun distance, and r_E the radius of the earth. This gives

$$\frac{N_\text{E}}{N_\nu} = \frac{\pi r_\text{E}^2}{4\pi r^2}$$

$$N_\text{E} = N_\nu\left(\frac{r_\text{E}}{2r}\right)^2 = \left(1.8\times10^{38}\ \text{neutrinos/s}\right)\left[\frac{6370\ \text{kg}}{2(150\times10^6\ \text{km})}\right] = 8.1\times10^{28}\ \text{neutrinos/s}.$$

(d) The area presented to the sun is the earth's cross-sectional area, so

$$A = \pi r_\text{E}^2 = \pi(6370\ \text{km})^2 = 1.3\times10^{18}\ \text{cm}^2.$$

(e) Dividing as specified gives

$$\frac{8.1\times10^{28}\ \text{neutrinos/s}}{1.3\times10^{18}\ \text{cm}^2} = 6\times10^{10}\ \text{neutrinos/s}\cdot\text{cm}^2.$$

EVALUATE: The number in part (e) is 60 billion neutrinos/s through each square centimeter! Most of them travel straight through without hitting anything.

43.53. **IDENTIFY** and **SET UP:** The amount of kinetic energy released is the energy equivalent of the mass change in the decay. $m_\text{e} = 0.0005486\ \text{u}$ and the atomic mass of ${}^{14}_{7}\text{N}$ is 14.003074 u. The energy equivalent of 1 u is 931.5 MeV. ${}^{14}\text{C}$ has a half-life of $T_{1/2} = 5730\ \text{y} = 1.81\times10^{11}\ \text{s}$. The RBE for an electron is 1.0.

EXECUTE: **(a)** ${}^{14}_{6}\text{C} \to \text{e}^- + {}^{14}_{7}\text{N} + \overline{\upsilon}_\text{e}.$

(b) The mass decrease is $\Delta M = m({}^{14}_{6}\text{C}) - [m_\text{e} + m({}^{14}_{7}\text{N})].$ Use nuclear masses, to avoid difficulty in accounting for atomic electrons. The nuclear mass of ${}^{14}_{6}\text{C}$ is $14.003242\ \text{u} - 6m_\text{e} = 13.999950\ \text{u}.$ The nuclear mass of ${}^{14}_{7}\text{N}$ is $14.003074\ \text{u} - 7m_\text{e} = 13.999234\ \text{u}.$

$\Delta M = 13.999950\ \text{u} - 13.999234\ \text{u} - 0.000549\ \text{u} = 1.67\times10^{-4}\ \text{u}.$ The energy equivalent of ΔM is 0.156 MeV.

(c) The mass of carbon is $(0.18)(75\ \text{kg}) = 13.5\ \text{kg}.$ From Example 43.9, the activity due to 1 g of carbon in a living organism is 0.255 Bq. The number of decay/s due to 13.5 kg of carbon is

$$(13.5\times10^3\ \text{g})(0.255\ \text{Bq/g}) = 3.4\times10^3\ \text{decays/s}.$$

(d) Each decay releases 0.156 MeV so 3.4×10^3 decays/s releases $530\ \text{MeV/s} = 8.5\times10^{-11}\ \text{J/s}.$

(e) The total energy absorbed in 1 year is $(8.5\times10^{-11}\ \text{J/s})(3.156\times10^{7}\ \text{s}) = 2.7\times10^{-3}\ \text{J}$. The absorbed dose is $\dfrac{2.7\times10^{-3}\ \text{J}}{75\ \text{kg}} = 3.6\times10^{-5}\ \text{J/kg} = 36\ \mu\text{Gy} = 3.6\ \text{mrad}$. With $\text{RBE} = 1.0$, the equivalent dose is $36\ \mu\text{Sv} = 3.6\ \text{mrem}$.

EVALUATE: Section 43.5 says that background radiation exposure is about 1.0 mSv per year. The radiation dose calculated in this problem is much less than this.

43.54. IDENTIFY and **SET UP:** $m_\pi = 264m_\text{e} = 2.40\times10^{-28}$ kg. The total energy of the two photons equals the rest mass energy $m_\pi c^2$ of the pion.

EXECUTE: **(a)** $E_\text{ph} = \frac{1}{2}m_\pi c^2 = \frac{1}{2}(2.40\times10^{-28}\ \text{kg})(3.00\times10^{8}\ \text{m/s})^2 = 1.08\times10^{-11}\ \text{J} = 67.5\ \text{MeV}$.

$$E_\text{ph} = \frac{hc}{\lambda},\ \text{so}\ \lambda = \frac{hc}{E_\text{ph}} = \frac{1.24\times10^{-6}\ \text{eV}\cdot\text{m}}{67.5\times10^{6}\ \text{eV}} = 1.84\times10^{-14}\ \text{m} = 18.4\ \text{fm}.$$

These are gamma ray photons, so they have $\text{RBE} = 1.0$.

(b) Each pion delivers $2(1.08\times10^{-11}\ \text{J}) = 2.16\times10^{-11}\ \text{J}$.

The absorbed dose is $200\ \text{rad} = 2.00\ \text{Gy} = 2.00\ \text{J/kg}$.

The energy deposited is $(25\times10^{-3}\ \text{kg})(2.00\ \text{J/kg}) = 0.050\ \text{J}$.

The number of π^0 mesons needed is $\dfrac{0.050\ \text{J}}{2.16\times10^{-11}\ \text{J/meson}} = 2.3\times10^{9}$ mesons.

EVALUATE: Note that charge is conserved in the decay since the pion is neutral. If the pion is initially at rest the photons must have equal momenta in opposite directions so the two photons have the same λ and are emitted in opposite directions. The photons also have equal energies since they have the same momentum and $E = pc$.

43.55. IDENTIFY and **SET UP:** The mass defect is E_B/c^2.

EXECUTE: $m_{^{11}_{6}\text{C}} - m_{^{11}_{5}\text{B}} - 2m_\text{e} = 1.03\times10^{-3}$ u. Decay is energetically possible.

EVALUATE: The energy released in the decay is $(1.03\times10^{-3}\ \text{u})(931.5\ \text{MeV/u}) = 0.959\ \text{MeV}$.

43.56. IDENTIFY: Assume the activity is constant during the year and use the given value of the activity to find the number of decays that occur in one year. Absorbed dose is the energy absorbed per mass of tissue. Equivalent dose is RBE times absorbed dose.

SET UP: For α particles, $\text{RBE} = 20$ (from Table 43.3).

EXECUTE: $(0.52\times10^{-6}\ \text{Ci})(3.7\times10^{10}\ \text{Bq/Ci})(3.156\times10^{7}\ \text{s}) = 6.07\times10^{11}\ \alpha$ particles. The absorbed dose is $\dfrac{(6.07\times10^{11})(4.0\times10^{6}\ \text{eV})(1.602\times10^{-19}\ \text{J/eV})}{(0.50\ \text{kg})} = 0.78\ \text{Gy} = 78\ \text{rad}$. The equivalent dose is $(20)(78\ \text{rad}) = 1600\ \text{rem}$.

EVALUATE: The equivalent dose is 16 Sv. This is large enough for significant damage to the person.

43.57. IDENTIFY and **SET UP:** One-half of the sample decays in a time of $T_{1/2}$.

EXECUTE: **(a)** $\dfrac{10\times10^{9}\ \text{y}}{200{,}000\ \text{y}} = 5.0\times10^{4}$.

(b) $\left(\frac{1}{2}\right)^{5.0\times10^4}$. This exponent is too large for most hand-held calculators. But $\left(\frac{1}{2}\right) = 10^{-0.301}$, so $\left(\frac{1}{2}\right)^{5.0\times10^4} = (10^{-0.301})^{5.0\times10^4} = 10^{-15{,}000}$.

EVALUATE: For $N = 1$ after 16 billion years, $N_0 = 10^{15{,}000}$. The mass of this many ^{99}Tc nuclei would be $(99)(1.66\times10^{-27}\ \text{kg})(10^{15{,}000}) = 10^{14{,}750}$ kg, which is immense, far greater than the mass of any star.

43.58. **IDENTIFY:** One rad of absorbed dose is 0.01 J/kg. The equivalent dose in rem is the absorbed dose in rad times the RBE. For part (c) apply $|dN/dt| = \lambda N$ with $\lambda = \dfrac{\ln 2}{T_{1/2}}$.

SET UP: For α particles, RBE = 20 (Table 43.3).

EXECUTE: **(a)** $(7.75\times10^{12})(4.77\times10^{6}\ \text{eV})(1.602\times10^{-19}\ \text{J/eV})/(70.0\ \text{kg}) = 0.0846\ \text{Gy} = 8.46\ \text{rad}$.

(b) $(20)(8.46\ \text{rad}) = 169\ \text{rem}$.

(c) $\left|\dfrac{dN}{dt}\right| = \dfrac{m}{Am_\text{p}}\dfrac{\ln(2)}{T_{1/2}} = 1.17\times10^{9}\ \text{Bq} = 31.6\ \text{mCi}$.

(d) $t = \dfrac{7.75\times10^{12}}{1.17\times10^{9}\ \text{Bq}} = 6.62\times10^{3}\ \text{s}$, which is about 1.8 hours.

EVALUATE: The time in part (d) is so small in comparison with the half-life that the decrease in activity of the source may be neglected.

43.59. **IDENTIFY:** Use $N = N_0 e^{-\lambda t}$ to relate the initial number of radioactive nuclei, N_0, to the number, N, left after time t.

SET UP: We have to be careful; after ^{87}Rb has undergone radioactive decay it is no longer a rubidium atom. Let N_{85} be the number of ^{85}Rb atoms; this number doesn't change. Let N_0 be the number of ^{87}Rb atoms on earth when the solar system was formed. Let N be the present number of ^{87}Rb atoms.

EXECUTE: The present measurements say that $0.2783 = N/(N + N_{85})$.

$(N + N_{85})(0.2783) = N$, so $N = 0.3856N_{85}$. The percentage we are asked to calculate is $N_0/(N_0 + N_{85})$.

N and N_0 are related by $N = N_0 e^{-\lambda t}$ so $N_0 = e^{+\lambda t}N$.

Thus $\dfrac{N_0}{N_0 + N_{85}} = \dfrac{Ne^{\lambda t}}{Ne^{\lambda t} + N_{85}} = \dfrac{(0.3855e^{\lambda t})N_{85}}{(0.3856e^{\lambda t})N_{85} + N_{85}} = \dfrac{0.3856e^{\lambda t}}{0.3856e^{\lambda t} + 1}$.

$$t = 4.6\times10^{9}\ \text{y};\ \lambda = \frac{0.693}{T_{1/2}} = \frac{0.693}{4.75\times10^{10}\ \text{y}} = 1.459\times10^{-11}\ \text{y}^{-1}.$$

$$e^{\lambda t} = e^{(1.459\times10^{-11}\ \text{y}^{-1})(4.6\times10^{9}\ \text{y})} = e^{0.06711} = 1.0694.$$

Thus $\dfrac{N_0}{N_0 + N_{85}} = \dfrac{(0.3856)(1.0694)}{(0.3856)(1.0694) + 1} = 29.2\%$.

EVALUATE: The half-life for ^{87}Rb is a factor of 10 larger than the age of the solar system, so only a small fraction of the ^{87}Rb nuclei initially present have decayed; the percentage of rubidium atoms that are radioactive is only a bit less now than it was when the solar system was formed.

43.60. **IDENTIFY:** Apply $N = N_0 e^{-\lambda t}$, with $\lambda = \dfrac{\ln 2}{T_{1/2}}$.

SET UP: Let 1 refer to $^{15}_{8}\text{O}$ and 2 refer to $^{19}_{8}\text{O}$. $\dfrac{N_1}{N_2} = \dfrac{e^{-\lambda_1 t}}{e^{-\lambda_2 t}}$, since N_0 is the same for the two isotopes.

$$e^{-\lambda t} = e^{-(\ln 2/T_{1/2})t} = (e^{-\ln 2})^{t/T_{1/2}} = (\tfrac{1}{2})^{t/T_{1/2}}.\ \frac{N_1}{N_2} = \left(\tfrac{1}{2}\right)^{(t/(T_{1/2})_1)/(t/(T_{1/2})_2)} = 2^{t\left(\frac{1}{(T_{1/2})_2} - \frac{1}{(T_{1/2})_1}\right)}.$$

EXECUTE: **(a)** After 3.0 min = 180 s, the ratio of the number of nuclei is

$$N_1/N_2 = \frac{2^{-180/122.2}}{2^{-180/26.9}} = 2^{(180)\left(\frac{1}{26.9} - \frac{1}{122.2}\right)} = 2^{(180)(0.02899)} = 37.2.$$

(b) After 12.0 min = 720 s, the ratio is $N_1/N_2 = 2^{(720)(002899)} = 1.92\times10^{6}$.

EVALUATE: The $^{19}_{8}\text{O}$ nuclei decay at a greater rate, so the ratio $N(^{15}_{8}\text{O})/N(^{19}_{8}\text{O})$ increases with time.

43.61. **IDENTIFY** and **SET UP:** Find the energy emitted and the energy absorbed each second. Convert the absorbed energy to absorbed dose and to equivalent dose.

EXECUTE: **(a)** First find the number of decays each second:

$2.6\times10^{-4}\ \text{Ci}\left(\dfrac{3.70\times10^{10}\ \text{decays/s}}{1\ \text{Ci}}\right)=9.6\times10^{6}$ decays/s. The average energy per decay is 1.25 MeV, and one-half of this energy is deposited in the tumor. The energy delivered to the tumor per second then is $\frac{1}{2}(9.6\times10^{6}\ \text{decays/s})(1.25\times10^{6}\ \text{eV/decay})(1.602\times10^{-19}\ \text{J/eV})=9.6\times10^{-7}\ \text{J/s}.$

(b) The absorbed dose is the energy absorbed divided by the mass of the tissue:

$$\frac{9.6\times10^{-7}\ \text{J/s}}{0.200\ \text{kg}}=(4.8\times10^{-6}\ \text{J/kg}\cdot\text{s})(1\ \text{rad/(0.01 J/kg)})=4.8\times10^{-4}\ \text{rad/s}.$$

(c) equivalent dose (REM) = RBE × absorbed dose (rad). In one second the equivalent dose is

$$(0.70)(4.8\times10^{-4}\ \text{rad})=3.4\times10^{-4}\ \text{rem}.$$

(d) $(200\ \text{rem})/(3.4\times10^{-4}\ \text{rem/s})=(5.9\times10^{5}\ \text{s})(1\ \text{h}/3600\ \text{s})=164\ \text{h}=6.9\ \text{days}.$

EVALUATE: The activity of the source is small so that absorbed energy per second is small and it takes several days for an equivalent dose of 200 rem to be absorbed by the tumor. A 200-rem dose equals 2.00 Sv and this is large enough to damage the tissue of the tumor.

43.62. **IDENTIFY:** This problem deals with nuclear fusion and the p-p I chain in the sun.

SET UP: The first reaction is $2{}^1_1\text{H}\rightarrow{}^2_1\text{H}+\beta^{+}+\nu_{\text{e}}$. Follow the directions for each part.

EXECUTE: **(a)** We want the total energy E_1 of the deuteron and neutrino. First find the energy Q released in the fusion reaction, treating the neutrino as essentially massless. From Table 43.2, the deuteron mass is m_{d} = 2.014102 u. $Q = (2m_{\text{p}} - m_{\text{d}})c^2$ = [2(1.007276 u) – 2.014102 u)(931.5 MeV/u) = 0.419 Mev. This is the energy shared between the deuteron, the positron, and the neutrino. But photons from electron-positron annihilation each had energy equal to the rest energy of the electron, so the positron must have been at rest after the first reaction. Therefore all the energy E_1 = 0.419 MeV is shared by the deuteron and neutrino.

(b) The neutrino is relativistic but the deuteron is not. If the neutrino is massless, then $E_{\text{v}} = pc$. Thus momentum conservation gives $p_{\text{d}} = p_{\text{v}}$, so $m_{\text{d}}v_{\text{d}} = E_{\text{v}}/c$. Energy conservation gives $E_{\text{d}} + E_{\text{v}} = E_1$, so $\frac{1}{2}m_{\text{d}}v_{\text{d}}^2+E_\nu=E_1.$

(c) We want E_{v}/E_1. Solve the momentum and energy equations in part (b) for E_{v}. This leads to the following quadratic equation:

$$E_\nu^2+2m_{\text{d}}c^2E_\nu-2m_{\text{d}}c^2E_1=0.$$

Using the positive root with the quadratic formula and doing some algebra gives

$$E_\nu=m_{\text{d}}c^2\left(-1+\sqrt{1+\frac{2E_1}{m_dc^2}}\right).$$

Using m_{d} = 2.014102 u and E_1 = 0.419 MeV, we E_{v}/E_1 = 0.41895/0.419 = 0.99989 = 99.989%.

(d) As we just saw, the neutrino essentially carries off all the energy. The first reaction occurs twice for each p-p I chain, so they carry off $2E_1$ = 2(0.419 MeV) = 0.838 MeV.

(e) In Section 43.8, it was calculated that the p-p chain releases 26.73 MeV of energy. So the percent that the neutrinos carry away is (0.838 MeV)/(26.73 MeV) = 3.1%.

EVALUATE: The 3.1% of the energy is large enough to be measurable. If neutrinos were not taken into account, the energy calculations for the sun would be off by about 3%.

43.63. **IDENTIFY:** This problem investigates the p-p II fusion chain in the sun.

SET UP: Follow the directions in each part and use Table 43.2 for nuclide masses. The third step of the chain is

$$^3_2\text{He} + {}^3_2\text{He} \to {}^7_4\text{Be} + \gamma.$$

EXECUTE: **(a)** We want the energy E_γ of the photon. Realize that $E_\gamma = Q$. From Table 43.2 we have:
Mass of He-3 = 3.016029 u
Mass of He-4 = 4.002603 u
Mass of Be-7 = 7.016930 u
The nuclide masses include the electrons, but since we'll be subtracting their effect subtracts out.
Therefore $E_\gamma = Q$ = (3.016029 u + 4.002603 u – 7.016930 u)(931.5 MeV/u) = 1.59 MeV.
(b) We want the energy E_ν of the neutrino in the following electron-capture of Be-7.

$$^7_4\text{Be} + \text{e}^- \to {}^7_3\text{Li} + \nu_\text{e}.$$

Using the given mass of Li-7 and the Be-7 mass from Table 43.2, we have

E_ν = (7.016930 u – 7.016003 u)(931.5 MeV/u) = 0.864 MeV.

(c) We want the energy Q that is released. Using the given reaction, we have

Q = [1.007825 u + 7.016003 u – 2(4.002603 u)](931.5 MeV/u) = 17.35 MeV.

(d) We want the speed v_α of the alpha particles. The alpha particles have equal speeds, so for each one K_α = (17.35 MeV)/2 = 8.675 MeV. Use the relativistic kinetic energy $K = mc^2(\gamma - 1)$. Solving for γ gives

$$\gamma = 1 + K_\alpha/m_\alpha c^2 = 1 + \frac{8.675 \text{ MeV}}{(4.002603 \text{ u})(931.5 \text{ MeV/u})} = 1.0023267.$$

Using this result gives

$$v = c\sqrt{1 - 1/\gamma^2} = 0.0681c.$$

(e) We want the total energy. The overall p-p II chain can be summarized as

$$4\,^1_1\text{H} + {}^4_2\text{He} \to 2\,^4_2\text{He} + 2\nu_\text{e} + \gamma.$$

Using masses from Table 43.2 gives Q = [4(1.007825 u) – 4.002603 u](931.5 MeV/u) = 26.7 MeV.
(f) The p-p I releases 26.73 MeV, so E_II/E_I = (26.7 MeV)/(26.73 MeV) = 99.9%. They are about the same.
(g) We want E_ν/E_tot. Using the results from (b) and (f) gives E_ν/E_I = (0.864 MeV)/(26.7 MeV) = 3.2%.

EVALUATE: The amount of energy per reaction is the same for p-p I and p-p II, but p-p II occurs less frequently so it contributes less to the sun's total energy production.

43.64. **IDENTIFY:** We are looking at the p-p III chain fusion in our sun.

SET UP: Follow the directions in each part and use Table 43.2 for nuclide masses.

EXECUTE: **(a)** We want the energy Q released. Looking at the reaction given in the problem, we see that Q = [4(1.007825 u) – 4.002603 u](931.5 MeV/u) = 26.73 MeV.
(b) We want the neutrino energy. The mass of B-8 is 8.024607 u and the mass of Be-8 + β^+ is 8.0053051 u. So E_ν = (8.024607 u – 8.0053051 u)(931.5 MeV/u) = 18.0 MeV.
(c) We want E_ν/E_tot. Using the results from (a) and (b) gives E_ν/E_tot = (18.0 MeV)/(26.73 MeV) = 67.3%.

EVALUATE: Comparing this result to those of problems 43.62 and 43.63, we see that in the p-p III chain the neutrino carries away a might higher percent of the energy than in the other two chains.

43.65. **IDENTIFY** and **SET UP:** The number of radioactive nuclei left after time t is given by $N = N_0 e^{-\lambda t}$. The problem says $N/N_0 = 0.29$; solve for t.

EXECUTE: $0.29 = e^{-\lambda t}$ so $\ln(0.29) = -\lambda t$ and $t = -\ln(0.29)/\lambda$. Example 43.9 gives

$$\lambda = 1.209 \times 10^{-4}\ \text{y}^{-1} \text{ for } {}^{14}\text{C. Thus } t = \frac{-\ln(0.29)}{1.209 \times 10^{-4}\ \text{y}} = 1.0 \times 10^4\ \text{y}.$$

EVALUATE: The half-life of ^{14}C is 5730 y, so our calculated t is about 1.75 half-lives, so the fraction remaining is around $\left(\frac{1}{2}\right)^{1.75} = 0.30.$

43.66. **IDENTIFY:** In terms of the number ΔN of cesium atoms that decay in one week and the mass

$$m = 1.0 \text{ kg}, \text{ the equivalent dose is } 3.5 \text{ Sv} = \frac{\Delta N}{m}((\text{RBE})_\gamma \text{E}_\gamma + (\text{RBE})_\text{e}\text{E}_\text{e}).$$

SET UP: $1 \text{ day} = 8.64\times10^4 \text{ s}$. $1 \text{ year} = 3.156\times10^7 \text{ s}$.

EXECUTE: $3.5 \text{ Sv} = \frac{\Delta N}{m}((1)(0.66 \text{ MeV}) + (1.5)(0.51 \text{ MeV})) = \frac{\Delta N}{m}(2.283\times10^{-13} \text{ J})$, so

$$\Delta N = \frac{(1.0 \text{ kg})(3.5 \text{ Sv})}{(2.283\times10^{-13} \text{ J})} = 1.535\times10^{13}. \ \lambda = \frac{\ln 2}{T_{1/2}} = \frac{0.693}{(30.07 \text{ y})(3.156\times10^7 \text{ sec/y})} = 7.30\times10^{-10} \text{ sec}^{-1}.$$

$$\Delta N = |dN/dt|t = \lambda N t, \text{ so } N = \frac{\Delta N}{\lambda t} = \frac{1.535\times10^{13}}{(7.30\times10^{-10} \text{ s}^{-1})(7 \text{ days})(8.64\times10^4 \text{ s/day})} = 3.48\times10^{16}.$$

EVALUATE: We have assumed that $|dN/dt|$ is constant during a time of one week. That is a very good approximation, since the half-life is much greater than one week.

43.67. **(a) IDENTIFY and SET UP:** Use $R = R_0 A^{1/3}$ to calculate the radius R of a ^2_1H nucleus. Calculate the Coulomb potential energy $U = \frac{1}{4\pi\epsilon_0}\frac{q_1 q_2}{r^2}$ of the two nuclei when they just touch.

EXECUTE: The radius of ^2_1H is $R = (1.2\times10^{-15} \text{ m})(2)^{1/3} = 1.51\times10^{-15} \text{ m}$. The barrier energy is the Coulomb potential energy of two ^2_1H nuclei with their centers separated by twice this distance:

$$U = \frac{1}{4\pi\epsilon_0}\frac{e^2}{r} = (8.988\times10^9 \text{ N}\cdot\text{m}^2/\text{C}^2)\frac{(1.602\times10^{-19} \text{ C})^2}{2(1.51\times10^{-15} \text{ m})} = 7.64\times10^{-14} \text{ J} = 0.48 \text{ MeV}.$$

(b) IDENTIFY and SET UP: Find the energy equivalent of the mass decrease.

EXECUTE: $^2_1\text{H} + ^2_1\text{H} \rightarrow ^3_2\text{He} + ^1_0\text{n}$

If we use neutral atom masses there are two electrons on each side of the reaction equation, so their masses cancel. The neutral atom masses are given in Table 43.2.

$$^2_1\text{H} + ^2_1\text{H} \text{ has mass } 2(2.014102 \text{ u}) = 4.028204 \text{ u}$$

$$^3_2\text{He} + ^1_0\text{n} \text{ has mass } 3.016029 \text{ u} + 1.008665 \text{ u} = 4.024694 \text{ u}$$

The mass decrease is $4.028204 \text{ u} - 4.024694 \text{ u} = 3.510\times10^{-3} \text{ u}$. This corresponds to a liberated energy of $(3.510\times10^{-3} \text{ u})(931.5 \text{ MeV/u}) = 3.270 \text{ MeV}$, or $(3.270\times10^6 \text{ eV})(1.602\times10^{-19} \text{ J/eV}) = 5.239\times10^{-13} \text{ J}$.

(c) IDENTIFY and SET UP: We know the energy released when two ^2_1H nuclei fuse. Find the number of reactions obtained with one mole of ^2_1H.

EXECUTE: Each reaction takes two ^2_1H nuclei. Each mole of D_2 has 6.022×10^{23} molecules, so 6.022×10^{23} pairs of atoms. The energy liberated when one mole of deuterium undergoes fusion is $(6.022\times10^{23})(5.239\times10^{-13} \text{ J}) = 3.155\times10^{11} \text{ J/mol}$.

EVALUATE: The energy liberated per mole is more than a million times larger than from chemical combustion of one mole of hydrogen gas.

43.68. **IDENTIFY:** The energy of the photon is equal to the sum of the kinetic energies of the proton and the neutron plus the binding energy of the deuteron.

SET UP: $\dfrac{hc}{\lambda} = K_p + K_n + E_B$. Since the proton and neutron have equal kinetic energy, this equation becomes $hc/\lambda = 2K_p + E_B = 2(\frac{1}{2} m_p v^2) + E_B$. Solving for v^2 gives $v^2 = \dfrac{hc}{m_p}\cdot\dfrac{1}{\lambda} - \dfrac{E_B}{m_p}$.

EXECUTE: **(a)** Figure 43.68 shows the graph of v^2 versus $1/\lambda$ for the data given in the problem. As shown above, the equation for v^2 versus $1/\lambda$ is $v^2 = \dfrac{hc}{m_p}\cdot\dfrac{1}{\lambda} - \dfrac{E_B}{m_p}$. The graph of v^2 versus $1/\lambda$ should be a straight line with slope equal to hc/m_p and y-intercept equal to $-E_B/m_p$. The slope of the best-fit straight line for our graph is 119.9 m^3/s^2 and the y-intercept is -2.156×10^{14} m^2/s^2.

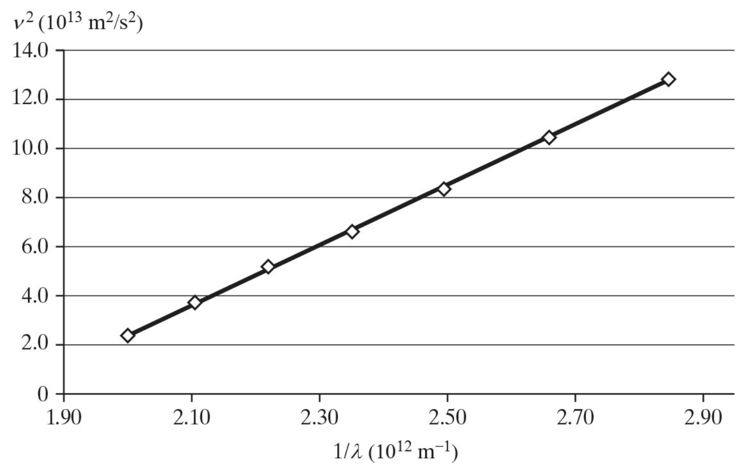

Figure 43.68

(b) Using the values for the slope and y-intercept for our graph, we have

$$hc/m_p = \text{slope} \rightarrow m_p = hc/(\text{slope}).$$

$$m_p = (6.626 \times 10^{-34}\ \text{J}\cdot\text{s})(2.998 \times 10^8\ \text{m/s})/(119.9\ \text{m}^3/\text{s}^2) = 1.66 \times 10^{-27}\ \text{kg}.$$

The y-intercept gives us the binding energy: $-E_B/m_p = y$-intercept, so $E_B = -m_p(y\text{-intercept})$.

$$E_B = -(1.66 \times 10^{-27}\ \text{kg})(-2.156 \times 10^{14}\ \text{m}^2/\text{s}^2) = 3.58 \times 10^{-13}\ \text{J} = 2.23 \times 10^6\ \text{eV} = 2.23\ \text{MeV}.$$

EVALUATE: The binding energy of a deuteron is $E_B = (m_{H\text{-}1} + m_n - m_D)c^2$, so $E_B = (1.007825\ \text{u} + 1.008665\ \text{u} - 2.014102\ \text{u})(931.5\ \text{MeV/u}) = 2.22$ MeV, so we are *very* close. Our results for m_p are *very* close to the accepted value for the proton mass of 1.67×10^{-27} kg.

43.69. **IDENTIFY:** Apply $\left|\dfrac{dN}{dt}\right| = \lambda N_0 e^{-\lambda t}$, with $\lambda = \dfrac{\ln 2}{T_{1/2}}$.

SET UP: $\ln\left|dN/dt\right| = \ln \lambda N_0 - \lambda t$.

EXECUTE: **(a)** A least-squares fit to log of the activity *vs.* time gives a slope of magnitude

$$\lambda = 0.5995\ \text{h}^{-1},\ \text{for a half-life of}\ \frac{\ln 2}{\lambda} = 1.16\ \text{h}.$$

(b) The initial activity is $N_0\lambda$, and this gives $N_0 = \dfrac{(2.00\times10^4\ \text{Bq})}{(0.5995\ \text{hr}^{-1})(1\ \text{hr}/3600\ \text{s})} = 1.20\times10^8$.

(c) $N = N_0 e^{-\lambda t} = 1.81\times10^6$.

EVALUATE: The activity decreases by about $\frac{1}{2}$ in the first hour, so the half-life is about 1 hour.

43.70. **IDENTIFY:** We cannot tell much from the raw data, but we know for radioactive decay of a single nuclide the activity rate A decreases as $A = A_0 e^{-\lambda t} = |dN/dt|$.

SET UP: $\left|\dfrac{dN}{dt}\right| = \lambda N = \lambda N_0 e^{-\lambda t}$ for a single nuclide. Since $A = A_0 e^{-\lambda t}$, it follows that $\ln A = \ln A_0 - \lambda t$.

Therefore if a single nuclide is present, a graph of $\ln A$ versus t should be a straight line with slope equal to $-\lambda$. We start with a graph of $\ln A$ versus t for the data given in the problem. Figure 43.70a shows this graph.

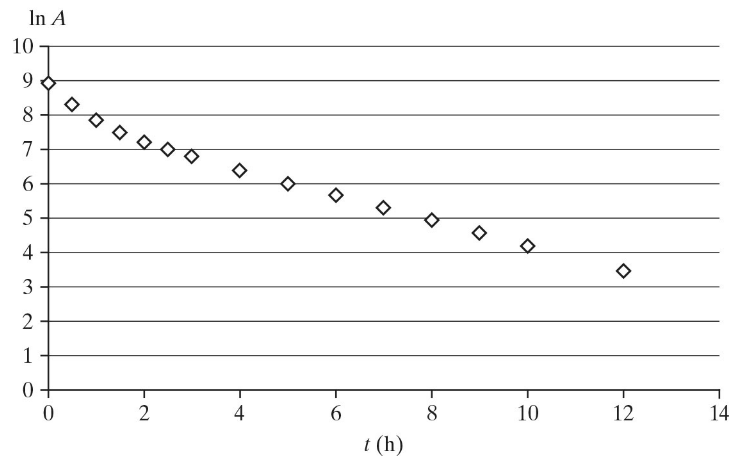

Figure 43.70a

EXECUTE: **(a)** The graph in Figure 43.70a is not a straight line, which suggests that the sample contains more than one nuclide. However after about 4.0 h, the graph does become a straight line. This suggests that a short-lived nuclide has decreased in activity, leaving only a single long-lived nuclide. To investigate the long-lived nuclide, we assume that nearly all the decays from 5.0 h on are due to this nuclide. So we make a graph of log A versus t for the decays from 5.0 h to 12.0 h. The result is shown in Figure 43.70b. This graph is a straight line, suggesting that our hypothesis is correct.

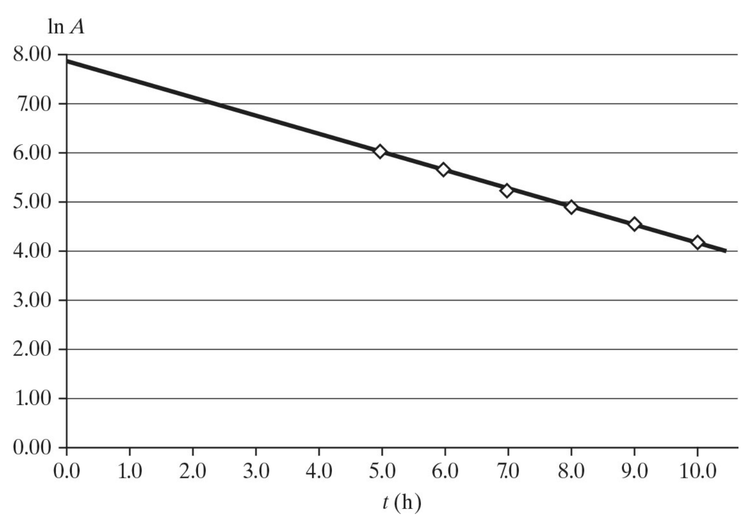

Figure 43.70b

To investigate the short-lived nuclide (or nuclides), we use our graph in Figure 43.70b to determine the activity of the long-lived nuclide during the first 4.0 h. We then subtract these numbers from the total decay rate to determine the decay rate due to the short-lived nuclide. The table shows these results.

Time (h)	Total rate (dec/s)	A (dec/s) for long-lived nuclide	ln A for long-lived nuclide	A (dec/s) for short-lived nuclide	ln A for short-lived nuclide
0	7500	2440	7.8	5060	8.53
0.5	4120	2320	7.75	1800	7.50
1.0	2570	1720	7.45	850	6.75
1.5	1790	1410	7.25	380	5.94
2.0	1350	1210	7.1	140	4.94
2.5	1070	992	6.9	78	4.36
3.0	872	6.7	812	60	4.09
4.0	596	572	6.35	24	3.18

Now we use the data in our table to graph ln A versus t for the short-lived nuclide. This graph is shown in Figure 43.70c. The last two points on the graph are unreliable because the decay rate is very small. For the rest of the points, the graph is a straight line. Therefore, since our two graphs of ln A versus t yield straight lines, it appears that our sample contains a minimum of two different nuclides, one with a short half-life and one with a long half-life.

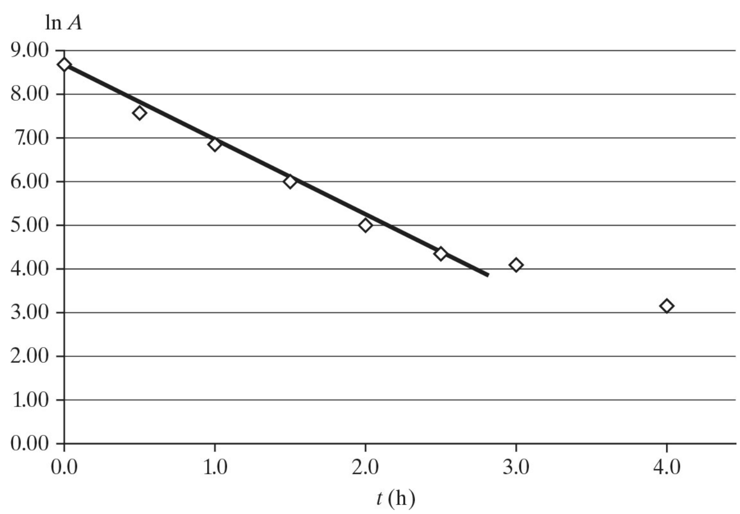

Figure 43.70c

(b) Long-lived nuclide: The slope of the graph in Figure 43.70b is –0.3636 h^{-1}, so λ_{long} = –slope = 0.3636 h^{-1}. Using $\lambda = (\ln 2)/T_{1/2}$, the half-life is $T_{1/2} = (\ln 2)/\lambda_{\text{long}} = (\ln 2)/(0.3636\ \text{h}^{-1}) = 1.9$ h.

Short-lived nuclide: The slope of the graph in Figure 43.70c is –1.78 h^{-1}, so λ_{short} = 1.78 h^{-1}. The half-life is $T_{1/2} = (\ln 2)/(1.78\ \text{h}^{-1}) = 0.39$ h.

(c) $\left|\dfrac{dN}{dt}\right| = \lambda N$, so $N = \dfrac{|dN/dt|}{\lambda}$.

Long-lived nuclide: $N_0 = (2440\ \text{Bq})/[(0.3636\ \text{h}^{-1})(1\ \text{h}/3600\ \text{s})] = 2.4 \times 10^7$ nuclei.

Short-lived nuclide: $N_0 = (5060\ \text{Bq})/[(1.78\ \text{h}^{-1})(1\ \text{h}/3600\ \text{s})] = 1.0 \times 10^7$ nuclei.

(d) Use $N = N_0 e^{-\lambda t}$ for each nuclide.

Long-lived nuclide: $N = N_0 e^{-\lambda_{\text{long}} t} = (2.4\times 10^7)\, e^{-(0.3636\ \text{h}^{-1})(5.0\ \text{h})} = 3.9\times 10^6$ nuclei.

Short-lived nuclide: $N = N_0 e^{-\lambda_{\text{short}} t} = (1.0\times 10^7)\, e^{-(1.78\ \text{h}^{-1})(5.0\ \text{h})} = 1.4\times 10^3$ nuclei.

EVALUATE: After 5.0 h, the number of shorter-lived nuclei is much less than the number of longer-lived nuclei. The ratio of the number of short-lived to the number of long-lived nuclei is $\dfrac{N_{\text{short}}}{N_{\text{long}}} = \dfrac{1.0\times 10^7}{2.4\times 10^7}\dfrac{e^{-\lambda_{\text{short}} t}}{e^{-\lambda_{\text{long}} t}} = 0.42 e^{-(\lambda_{\text{short}} - \lambda_{\text{long}})t}$. Since $\lambda_{\text{short}} > \lambda_{\text{long}}$, this ratio keeps decreasing with time.

43.71. IDENTIFY: Apply $A = A_0 e^{-\lambda t}$, where A is the activity and $\lambda = (\ln 2)/T_{1/2}$. This equation can be written as $A = A_0 2^{-(t/T_{1/2})}$. The activity of the engine oil is proportional to the mass worn from the piston rings.

SET UP: $1\ \text{Ci} = 3.7\times 10^{10}\ \text{Bq}$.

EXECUTE: The activity of the original iron, after 1000 hours of operation, would be $(9.4\times 10^{-6}\ \text{Ci})\,(3.7\times 10^{10}\ \text{Bq/Ci})2^{-(1000\ \text{h})/[(45\ \text{d})(24\ \text{h/d})]} = 1.8306\times 10^5\ \text{Bq}$. The activity of the oil is 84 Bq, or 4.5886×10^{-4} of the total iron activity, and this must be the fraction of the mass worn, or mass of 4.59×10^{-2} g. The rate at which the piston rings lost their mass is then 4.59×10^{-5} g/h.

EVALUATE: This method is very sensitive and can measure very small amounts of wear.

43.72. IDENTIFY and SET UP: Follow the procedure outlined in the problem. Solve the differential equation $dN_2/dt = \lambda_1 N_{10} e^{-\lambda_1 t} - \lambda_2 N_2$, where N_{10} is the initial number of ${}^{234}_{92}\text{U}$ nuclei and N_2 is the number of ${}^{230}_{88}\text{Th}$ nuclei. Assume a solution of the form $N_2(t) = N_{10}(h_1 e^{-\lambda_1 t} + h_2 e^{-\lambda_2 t})$ and follow the suggestions in the problem.

EXECUTE: (a) $N_2(0) = 0 = N_{10}(h_1 + h_2) \rightarrow h_2 = -h_1$.

(b) Take the derivative of $N_2(t)$: $dN_2/dt = N_{10}(-\lambda_1 h_1 e^{-\lambda_1 t} - \lambda_2 h_2 e^{-\lambda_2 t})$. Now substitute dN/dt and $N(t)$ into the original differential equation.

$$N_{10}(-\lambda_1 h_1 e^{-\lambda_1 t} - \lambda_2 h_2 e^{-\lambda_2 t}) = \lambda_1 N_{10} e^{-\lambda_1 t} - \lambda_2 (h_1 e^{-\lambda_1 t} + h_2 e^{-\lambda_2 t}).$$

Collect coefficients of $e^{-\lambda_1 t}$ and $e^{-\lambda_2 t}$.

$$N_{10}(\lambda_1 h_1 + \lambda_1 - \lambda_2 h_2)e^{-\lambda_1 t} + N_{10}(\lambda_2 h_2 - \lambda_2 h_2)e^{-\lambda_2 t} = 0.$$

Setting the coefficients equal to zero gives $h_1 = \dfrac{\lambda_1}{\lambda_2 - \lambda_1}$. Putting this result into the equation for $N_2(t)$ and using the fact that $h_2 = -h_1$ gives $N_2(t) = \dfrac{\lambda_1}{\lambda_2 - \lambda_1}(e^{-\lambda_1 t} - e^{-\lambda_2 t})$.

(c) The initial number of ${}^{234}_{92}\text{U}$ atoms is

$$N_{10} = (30.0\ \text{g})[(6.022\times 10^{23}\ \text{atoms})/(234\ \text{g})] = 7.7205\times 10^{22}\ \text{atoms}.$$

Using $\lambda = (\ln 2)/T_{1/2}$, we get $\lambda_1 = (\ln 2)/(2.46\times 10^5\ \text{y})$ and $\lambda_2 = (\ln 2)/(7.54\times 10^4\ \text{y})$, which gives $\dfrac{\lambda_1}{\lambda_2 - \lambda_1} = 0.44197$. At time $t = 2.46\times 10^5$ y, the number N_2 of ${}^{230}_{88}\text{Th}$ atoms is

$$N_2 = (7.7205\times 10^{22}\ \text{atoms})(0.44197)[e^{-(\ln 2)} - e^{(\ln 2)(2.46)/(0.754)}] = 1.3506\times 10^{22}\ \text{atoms}.$$

The mass M of all these ${}^{230}_{88}\text{Th}$ atoms is

$$M = (1.3506\times 10^{22}\ \text{atoms})[(1\ \text{mol})/(6.022\times 10^{23}\ \text{atoms})][(230\ \text{g})/\text{mol}] = 5.16\ \text{g}.$$

EVALUATE: The ${}^{234}_{92}\text{U}$ decays with a half-life of 2.46×10^5 y, so at this time half the original uranium, or 15.0 g, is still left but only 5.16 g of ${}^{230}_{88}\text{Th}$ is present because it has continued to decay after being formed.

43.73. IDENTIFY and SET UP: The reaction is ${}^{130}_{52}\text{Te} + \text{X} \rightarrow {}^{131}_{52}\text{Te}.$

EXECUTE: X must have no charge since Z remains 52, and it must increase the atomic weight from 130 to 131, so it must be a neutron, which is choice (a).

EVALUATE: The other reactions in the choices all start out with the wrong isotope, so they cannot be correct.

43.74. IDENTIFY and SET UP: The reaction is ${}^{131}_{52}\text{Te} \rightarrow {}^{131}_{53}\text{I} + \text{X}.$

EXECUTE: The mass number 131 does not change, but the atomic number goes from 52 to 53, so the nucleus gained a charge of +1 (or lost a charge of –1). Therefore X must must be a β^- particle, which is choice (b).

EVALUATE: Alpha decay would change the mass number A by 4 units, β^+ decay would decrease the atomic number Z by 1 unit, and gamma decay would not affect Z.

43.75. IDENTIFY and SET UP: A thyroid treatment administers 3.7 GBq of ${}^{131}_{53}\text{I},$ which has a half-life of 8.04 days. $\lambda = (\ln 2)/T_{1/2}$ and $|dN/dt| = \lambda N = \dfrac{\ln 2}{T_{1/2}} N.$

EXECUTE: Solve for N and put in the numbers.

$N = \dfrac{T_{1/2}\,|dN/dt|}{\ln 2}$ = (8.04 d)(24 ×3600 s/d)(3.7 ×10^9 decays/s)/(ln 2) = 3.7 ×10^{15} atoms, which is choice (d).

EVALUATE: This amount is (3.7 ×10^{15} atoms)/(6.02 ×10^{23} atoms/mol) = 6.1 ×10^{-9} mol ≈ 6 nanomoles.

43.76. IDENTIFY and SET UP: The reaction is ${}^{123}_{52}\text{Te} + \text{p} \rightarrow {}^{123}_{53}\text{I} + \text{n}$. Calculate the reaction energy Q to find out if the reaction is exoergic or endoergic.

EXECUTE: $Q = (M_{\text{Te}} + M_{\text{p}} - M_{\text{I}} - M_{\text{n}})c^2$. Using the values from the problem gives
Q = (122.904270 u + 1.007825 u – 122.905589 u – 1.008665 u)c^2 = –0.002159 uc^2, so the reaction is endoergic. We must put in energy to cause the reaction, which means that the proton must have a minimum kinetic energy, so choice (d) is correct.

EVALUATE: $|Q|$ = (0.002159 u)(931.5 MeV/u) = 2.011 MeV, so the proton must have at least 2.011 MeV of kinetic energy to cause the reaction.

43.77. IDENTIFY and SET UP: ${}^{131}_{53}\text{I}$ undergoes β^- decay, but ${}^{123}_{53}\text{I}$ undergoes gamma decay.

EXECUTE: From Table 43.3 we see that the RBE for gamma rays is 1, but the RBE for electrons is 1.0-1.5, so the electrons could cause more tissue damage than the gamma rays. This makes choice (b) the best one.

EVALUATE: The higher the RBE, the more likely it is that tissue damage could occur.

44

PARTICLE PHYSICS AND COSMOLOGY

VP44.1.1. **IDENTIFY:** This problem is about a cyclotron accelerating protons.

SET UP and **EXECUTE:** **(a)** We want the frequency. Use Eq. (44.7).

$$f = \frac{eB}{2\pi m} = \frac{e(0.600\ \text{T})}{2\pi m_\text{p}} = 9.15\ \text{MHz}.$$

(b) We want the maximum kinetic energy of the proton. Use Eq. (44.8) with $B = 0.600$ T and $R = 0.800$ m.

$$K_\text{max} = \frac{e^2B^2R^2}{2m_\text{p}} = 11.0\ \text{MeV}.$$

(c) We want the proton's speed. The rest energy of the proton is 938 MeV which is much greater than the kinetic energy of 11 MeV, so we do not have to use the relativistic equation. Solving $K = \frac{1}{2}mv^2$ for v gives

$$v = \sqrt{2K/m_\text{p}} = 4.60\times10^7\ \text{m/s} = 0.153c.$$

EVALUATE: Since $v \approx 15\%$ of c, it is reasonable not to use relativity. If we had used relativity, our result would be

$$K = mc^2(\gamma - 1) \rightarrow \gamma = 1.012$$

$$v = c\sqrt{1 - 1/\gamma^2} = 0.152c.$$

The percent difference between the two answers is 0.001/0.152 = 0.66%, which is extremely small.

VP44.1.2. **IDENTIFY:** This problem is about a cyclotron accelerating hydrogen ions (protons).

SET UP and **EXECUTE:** **(a)** We want the radius R. $R = m_\text{p}v/eB$. Using $B = 0.460$ T and the given speed, we get $R = 0.136$ m.

(b) We want the angular frequency. Use Eq. (44.7) with $q = e$ and $B = 0.460$ T, which gives $\omega = eB/m = 4.41 \times 10^7$ rad/s.

EVALUATE: This angular frequency is rather small compared to many modern cyclotrons.

VP44.1.3. **IDENTIFY:** This problem deals with the operation of a cyclotron.

SET UP and **EXECUTE:** **(a)** We want the magnetic field. The rest energy of the proton is 938 MeV and its kinetic energy here is 80.0 keV, which is much less than its rest energy. Therefore we do not need to use special relativity. We use Eq. (44.8), with $R = (11.4\ \text{cm})/2$ and $K_\text{max} = 80.0$ keV, and solve for B, which gives

$$B = \frac{\sqrt{2m_\text{p}K_\text{max}}}{eR} = 0.717\ \text{T}.$$

(b) We want the frequency. Use Eq. (44.7) with $B = 0.717$ T and $q = e$.

$$f = \frac{eB}{2\pi m} = \frac{e(0.717\ \text{T})}{2\pi m_\text{p}} = 10.9\ \text{MHz}.$$

EVALUATE: Modern cyclotrons produce much greater kinetic energy, but after all, this was the first one.

VP44.1.4. **IDENTIFY:** This problem deals with the operation of a cyclotron.

SET UP and **EXECUTE:** **(a)** We want the magnetic field and know that the frequency is 5.80 MHz. Use Eq. (44.7) and solve for B using $q = 2e$ and the given mass of an alpha particle.

$$B = \frac{2\pi m_\alpha f}{2e} = 0.756\ \text{T}.$$

(b) We want the kinetic energy when $R = 0.650$ m. Using Eq. (44.8) with $B = 0.756$ T gives

$$K_{\text{max}} = \frac{(2e)^2 B^2 R^2}{2m_\alpha} = 11.6\ \text{MeV}.$$

EVALUATE: A magnetic field of 0.756 T is certainly physically reasonable in a physics laboratory.

VP44.3.1. **IDENTIFY:** This problem deals with the available energy when particles collide.

SET UP and **EXECUTE:** We follow the procedure of Example 44.2.

(a) We want the available energy E_a. The total available energy must be the total rest energy in the center-of-momentum frame.

$$E_{\text{a}} = 2m_{\text{p}}c^2 + m_{n'}c^2 = 2(938\ \text{MeV}) + 958\ \text{MeV} = 2834\ \text{MeV}.$$

(b) We want the kinetic energy K of the incoming proton. First use Eq. (44.10) to find E_m (the total energy of the incoming proton). Then use $E_m = K + m_pc^2$ to find K.

$$E_m = \frac{E_{\text{a}}^2}{2m_{\text{p}}c^2} - m_{\text{p}}c^2 = K + m_{\text{p}}c^2$$

$$K = \frac{E_{\text{a}}^2}{2m_{\text{p}}c^2} - 2m_{\text{p}}c^2$$

Using $E_a = 2834$ MeV and $m_pc^2 = 938$ MeV gives us $K = 2410$ MeV = 2.41 GeV.

EVALUATE: Colliding beams would require far less kinetic energy because nearly all the incoming kinetic energy is available energy.

VP44.3.2. **IDENTIFY:** This problem deals with the available energy during collisions.

SET UP and **EXECUTE:** **(a)** We want E_a. The minimum available energy is the rest energy of the particles after the collision. $E_a = m_pc^2 + m_\Delta c^2 = 938\ \text{MeV} + 1232\ \text{MeV} = 2170\ \text{MeV} = 2.17\ \text{GeV}$.

(b) We want the kinetic energy. Use the same method as in problem VP44.3.1.

$$K = \frac{E_{\text{a}}^2}{2m_{\text{p}}c^2} - 2m_{\text{p}}c^2$$

Using $E_a = 2170$ MeV and $m_pc^2 = 938$ MeV gives $K = 634$ MeV.

EVALUATE: The incoming proton could have more than 634 MeV of kinetic energy. In that case, the products would each have kinetic energy.

VP44.3.3. **IDENTIFY:** This problem deals with the available energy during collisions.

SET UP and **EXECUTE:** **(a)** We want E_a. The minimum available energy is the rest energy of the product (the Δ^0), which is 1232 MeV.

(b) We want the minimum kinetic energy K of the pion. The target and incident particle have different masses, so use Eq. (44.9) to find the available energy. Then use this to find E_m, and finally use $E_m = K + mc^2$ to find K.

The quantities in Eq. (44.9) are:

M = target = proton, so $Mc^2 = 938$ MeV

m = incident particle = π^-, so $mc^2 = 140$ MeV

Using the result of part (a), Eq. (44.9) gives

$$(1232\ \text{MeV})^2 = 2(938\ \text{MeV})E_m + (938\ \text{MeV})^2 + (140\ \text{MeV})^2$$

$$E_m = 329.6 \text{ MeV}.$$

Now use $E_m = K + mc^2$ to find K.

329.6 MeV = K + 140 MeV, which gives K = 190 MeV.

EVALUATE: Notice that the kinetic energy is a significant fraction of E_m.

VP44.3.4. **IDENTIFY:** This problem deals with the available energy during collisions.

SET UP and **EXECUTE:** **(a)** We want E_a. E_m = 7000 GeV and m_pc^2 = 938 MeV, so $E_m >> m_pc^2$. Therefore we use Eq. (44.11). Using the given rest energies gives

$$E_a = \sqrt{2\,mc^2 E_m} = \sqrt{2(938 \text{ MeV})(7000 \text{ GeV})} = 115 \text{ GeV}.$$

(b) We want the minimum mass of particle X. E_a is at *least* equal to the rest energy of the products of the collision, which are 2 protons and particle X. So 115 GeV = 2(938 MeV) + m_Xc^2. This gives m_X = 113 GeV/c^2.

EVALUATE: Particle X is 120 times heavier than the proton.

VP44.9.1. **IDENTIFY:** This problem concerns the red shift.

SET UP and **EXECUTE:** **(a)** The target variable is z.

$$z = \frac{\Delta\lambda}{\lambda} = \frac{725 \text{ nm} - 656.3 \text{ nm}}{656.3 \text{ nm}} = 0.105.$$

(b) We want the speed. Use Eq. (44.14) with the given wavelengths.

$$v = \frac{(\lambda_0/\lambda_s)^2 - 1}{(\lambda_0/\lambda_s)^2 + 1}c = \frac{(725/656.3)^2 - 1}{(725/656.3)^2 + 1}c = 0.0992c.$$

EVALUATE: The fact that we have a red shift instead of a blue shift tells us that the galaxy is receding from us at 9.92% the speed of light.

VP44.9.2. **IDENTIFY:** This problem is about the red shift of a galaxy.

SET UP: Eq. (44.13) applies.

EXECUTE: **(a)** We want wavelength that we observe. Use Eq. (44.13).

$$\lambda_0 = \lambda_s\sqrt{\frac{c+v}{c-v}} = (396.9 \text{ nm})\sqrt{\frac{c+0.0711c}{c-0.0711c}} = 426 \text{ nm}.$$

(b) We want z.

$$z = \frac{\Delta\lambda}{\lambda} = \frac{426 \text{ nm} - 396.9 \text{ nm}}{396.9 \text{ nm}} = 0.0738.$$

EVALUATE: Since v is only about 7% the speed of light, the red shift is not very large.

VP44.9.3. **IDENTIFY:** This problem requires the use of Hubble's law.

SET UP: Hubble's law: $v = H_0 r$, where H_0 = (68 km/s)/Mpc. The target variable is the distance to the galaxy.

EXECUTE: **(a)** $v = 0.0992c$. Apply Hubble's law using the measured speed.

$$r = \frac{v}{H_0} = \frac{0.0992c}{68\,\dfrac{\text{km/s}}{\text{Mpc}}} = 440 \text{ Mpc} = 4.4\times10^8 \text{ pc}.$$

(b) $v = 0.0711c$. Use the same approach as in part (a).

$$r = \frac{v}{H_0} = \frac{0.0711c}{68\,\dfrac{\text{km/s}}{\text{Mpc}}} = 310 \text{ Mpc} = 3.1\times10^8 \text{ pc}.$$

EVALUATE: Speeds can be determined quite easily using spectral analysis, but H_0 is not so easy to measure. These distances are only as accurate as H_0.

VP44.9.4. **IDENTIFY:** This problem requires the use of Hubble's law and the red shift.

SET UP: Hubble's law: $v = H_0 r$, where $H_0 = (68\text{ km/s})/\text{Mpc}$.

EXECUTE: **(a)** We want the speed of recession of the galaxy. Use Eq. (44.14).

$$v = \frac{(\lambda_0/\lambda_s)^2 - 1}{(\lambda_0/\lambda_s)^2 + 1}c = \frac{(666/615)^2 - 1}{(666/615)^2 + 1}c = 0.0795c = 2.38\times10^7\text{ m/s}.$$

(b) We want the distance to the galaxy. Use Hubble's law.

$$r = \frac{v}{H_0} = \frac{2.38\times10^7\text{ m/s}}{68\,\frac{\text{km/s}}{\text{Mpc}}} = 350\text{ Mpc} = 3.5\times10^8\text{ pc}.$$

EVALUATE: Using 1 pc = 3.26 ly, we find that this galaxy is 1.1 billion light-years from us!

44.1. **IDENTIFY:** The antimatter annihilates with an equal amount of matter.

SET UP: The energy of the matter is $E = (\Delta m)c^2$.

EXECUTE: Putting in the numbers gives

$$E = (\Delta m)c^2 = (400\text{ kg} + 400\text{ kg})(3.00\times10^8\text{ m/s})^2 = 7.2\times10^{19}\text{ J}.$$

This is about 70% of the annual energy use in the U.S.

EVALUATE: If this huge amount of energy were released suddenly, it would blow up the *Enterprise*! Getting useable energy from matter-antimatter annihilation is not so easy to do!

44.2. **IDENTIFY:** The energy (rest mass plus kinetic) of the muons is equal to the energy of the photons.

SET UP: $\gamma + \gamma \to \mu^+ + \mu^-$, $E = hc/\lambda$. $K = (\gamma - 1)mc^2$.

EXECUTE: **(a)** $\gamma + \gamma \to \mu^+ + \mu^-$. Each photon must have energy equal to the rest mass energy of a μ^+ or a μ^-: $\frac{hc}{\lambda} = 105.7\times10^6\text{ eV}$. $\lambda = \frac{(4.136\times10^{-15}\text{ eV}\cdot\text{s})(2.998\times10^8\text{ m/s})}{105.7\times10^6\text{ eV}} = 1.17\times10^{-14}\text{ m} = 0.0117\text{ pm}.$

Conservation of linear momentum requires that the μ^+ and μ^- move in opposite directions with equal speeds.

(b) $\lambda = \frac{0.0117\text{ pm}}{2}$, so each photon has energy $2(105.7\text{ MeV}) = 211.4\text{ MeV}$. The energy released in the reaction is $2(211.4\text{ MeV}) - 2(105.7\text{ MeV}) = 211.4\text{ MeV}$. The kinetic energy of each muon is half this, 105.7 MeV. Using $K = (\gamma - 1)mc^2$ gives $\gamma - 1 = \frac{K}{mc^2} = \frac{105.7\text{ MeV}}{105.7\text{ MeV}} = 1$. $\gamma = 2$. $\gamma = \frac{1}{\sqrt{1 - v^2/c^2}}$.

$$\frac{v^2}{c^2} = 1 - \frac{1}{\gamma^2}.\quad v = \sqrt{\frac{3}{4}}c = 0.866c = 2.60\times10^8\text{ m/s}.$$

EVALUATE: The muon speeds are a substantial fraction of the speed of light, so special relativity must be used.

44.3. **IDENTIFY:** The energy released is the energy equivalent of the mass decrease that occurs in the decay.

SET UP: The mass of the pion is $m_{\pi^+} = 270m_e$ and the mass of the muon is $m_{\mu^+} = 207m_e$. The rest energy of an electron is 0.511 MeV.

EXECUTE: **(a)** $\Delta m = m_{\pi+} - m_{\mu+} = 270m_e - 207m_e = 63m_e \Rightarrow E = 63(0.511\text{ MeV}) = 32\text{ MeV}.$

EVALUATE: **(b)** A positive muon has less mass than a positive pion, so if the decay from muon to pion was to happen, you could always find a frame where energy was not conserved. This cannot occur.

44.4. **IDENTIFY:** In the annihilation the total energy of the proton and antiproton is converted to the energy of the two photons.

SET UP: The rest energy of a proton or antiproton is 938.3 MeV. Conservation of linear momentum requires that the two photons have equal energies. The energy of a photon is $E = hf$, and $f\lambda = c$.

EXECUTE: **(a)** The energy will be the proton rest energy, 938.3 MeV, so $hf = 938.3$ MeV. Solving for f gives $f = (938.3\times10^{6}\text{ eV})/(4.136\times10^{-15}\text{ eV}\cdot\text{s}) = 2.27\times10^{23}$ Hz. The wavelength is

$$\lambda = c/f = 1.32\times10^{-15}\text{ m} = 1.32\text{ fm}.$$

(b) The energy of each photon will be $938.3\text{ MeV} + 620\text{ MeV} = 1558\text{ MeV}$, so $f = (1558\text{ MeV})/h$ $= 3.77\times10^{23}$ Hz. $\lambda = c/f = 7.96\times10^{-16}\text{ m} = 0.796$ fm.

EVALUATE: When the initial kinetic energy of the proton and antiproton increases, the wavelength of the photons decreases.

44.5. **IDENTIFY:** The kinetic energy of the alpha particle is due to the mass decrease.

SET UP and **EXECUTE:** ${}^{1}_{0}\text{n} + {}^{10}_{5}\text{B} \rightarrow {}^{7}_{3}\text{Li} + {}^{4}_{2}\text{He}$. The mass decrease in the reaction is

$m({}^{1}_{0}\text{n}) + m({}^{10}_{5}\text{B}) - m({}^{7}_{3}\text{Li}) - m({}^{4}_{2}\text{He}) = 1.008665\text{ u} + 10.012937\text{ u} - 7.016005\text{ u} - 4.002603\text{ u} = 0.002994\text{ u}$ and the energy released is $E = (0.002994\text{ u})(931.5\text{ MeV/u}) = 2.79\text{ MeV}$. Assuming the initial momentum is zero, $m_{\text{Li}}v_{\text{Li}} = m_{\text{He}}v_{\text{He}}$ and $v_{\text{Li}} = \dfrac{m_{\text{He}}}{m_{\text{Li}}}v_{\text{He}}$. $\frac{1}{2}m_{\text{Li}}v_{\text{Li}}^2 + \frac{1}{2}m_{\text{He}}v_{\text{He}}^2 = E$ becomes

$$\frac{1}{2}m_{\text{Li}}\left(\frac{m_{\text{He}}}{m_{\text{Li}}}\right)^2 v_{\text{He}}^2 + \frac{1}{2}m_{\text{He}}v_{\text{He}}^2 = E \text{ and } v_{\text{He}} = \sqrt{\frac{2E}{m_{\text{He}}}\left(\frac{m_{\text{Li}}}{m_{\text{Li}} + m_{\text{He}}}\right)}.\ E = 4.470\times10^{-13}\text{ J}.$$

$$m_{\text{He}} = 4.002603\text{ u} - 2(0.0005486\text{ u}) = 4.0015\text{ u} = 6.645\times10^{-27}\text{ kg}.$$

$$m_{\text{Li}} = 7.016005\text{ u} - 3(0.0005486\text{ u}) = 7.0144\text{ u}.\text{ This gives } v_{\text{He}} = 9.26\times10^{6}\text{ m/s}.$$

EVALUATE: The speed of the alpha particle is considerably less than the speed of light, so it is not necessary to use the more complicated relativistic formulas.

44.6. **IDENTIFY:** The range is limited by the lifetime of the particle, which itself is limited by the uncertainty principle.

SET UP: $\Delta E\Delta t = \hbar/2$.

EXECUTE: $\Delta t = \dfrac{\hbar}{2\Delta E} = \dfrac{(4.136\times10^{-15}\text{ eV}\cdot\text{s}/2\pi)}{2(783\times10^{6}\text{ eV})} = 4.20\times10^{-25}$ s. The range of the force is

$$c\Delta t = (2.998\times10^{8}\text{ m/s})(4.20\times10^{-25}\text{ s}) = 1.26\times10^{-16}\text{ m} = 0.126\text{ fm}.$$

EVALUATE: This range is less than the diameter of an atomic nucleus.

44.7. **IDENTIFY:** This problem is about the available energy during a collision of equal-mass particles.

SET UP: We are comparing the available kinetic energy if the target is stationary or if we have colliding beams.

EXECUTE: **(a)** Stationary target. Use Eq. 44.10 and solve for K.

$$E_{\text{a}}^2 = 2mc^2(mc^2 + K)$$

$$K = \frac{E_{\text{a}}^2}{2mc^2} - mc^2 = \frac{(2\text{ TeV})^2}{2(938\text{ MeV})} - 938\text{ MeV} = 2130\text{ TeV}.$$

(b) Colliding beams. The available energy is the kinetic energy minus the rest energy of the two protons.

$$E_{\text{a}} = 2K - 2m_{\text{p}}c^2$$

$$K = \frac{E_{\text{a}} + 2m_{\text{p}}c^2}{2} = \frac{2.00\text{ TeV} + 2(938\text{ MeV})}{2} = 1.00\text{ TeV}.$$

EVALUATE: By using colliding beams we need less than 1/1000 the kinetic energy than with a stationary target.

44.8. **IDENTIFY:** With a stationary target, only part of the initial kinetic energy of the moving electron is available. Momentum conservation tells us that there must be nonzero momentum after the collision, which means that there must also be leftover kinetic energy. Therefore not all of the initial energy is available.

SET UP: The available energy is given by $E_a^2 = 2mc^2(E_m + mc^2)$ for two particles of equal mass when one is initially stationary. In this case, the initial kinetic energy $(30.0\text{ GeV} = 30{,}000\text{ MeV})$ is much more than the rest energy of the electron (0.511 MeV), so the formula for available energy reduces to

$$E_a = \sqrt{2mc^2 E_m}.$$

EXECUTE: **(a)** Using the formula for available energy gives

$$E_a = \sqrt{2mc^2 E_m} = \sqrt{2(0.511\text{ MeV})(30.0\text{ GeV})} = 175\text{ MeV}.$$

(b) For colliding beams of equal mass, each particle has half the available energy, so each has 87.5 MeV. The *total* energy is twice this, or 175 MeV.

EVALUATE: Colliding beams provide considerably more available energy to do experiments than do beams hitting a stationary target. With a stationary electron target in part (a), we had to give the moving electron 30,000 MeV of energy to get the same available energy that we got with only 175 MeV of energy with the colliding beams.

44.9. **IDENTIFY** and **SET UP:** The angular frequency is $\omega = |q|B/m$ so $B = m\omega/|q|$. And since $\omega = 2\pi f$, this becomes $B = 2\pi mf/|q|$.

EXECUTE: **(a)** A deuteron is a deuterium nucleus $({}^2_1\text{H})$. Its charge is $q = +e$. Its mass is the mass of the neutral ${}^2_1\text{H}$ atom (Table 43.2) minus the mass of the one atomic electron:

$m = 2.014102\text{ u} - 0.0005486\text{ u} = 2.013553\text{ u}(1.66054\times10^{-27}\text{ kg/1 u}) = 3.344\times10^{-27}\text{ kg}.$

$$B = \frac{2\pi mf}{|q|} = \frac{2\pi(3.344\times10^{-27}\text{ kg})(9.00\times10^{6}\text{ Hz})}{1.602\times10^{-19}\text{ C}} = 1.18\text{ T}.$$

(b) Eq. (44.8): $K = \dfrac{q^2B^2R^2}{2m} = \dfrac{[(1.602\times10^{-19}\text{ C})(1.18\text{ T})(0.320\text{ m})]^2}{2(3.344\times10^{-27}\text{ kg})}.$

$$K = 5.471\times10^{-13}\text{ J} = (5.471\times10^{-13}\text{ J})(1\text{ eV}/1.602\times10^{-19}\text{ J}) = 3.42\text{ MeV}.$$

$$K = \tfrac{1}{2}mv^2,\text{ so } v = \sqrt{\frac{2K}{m}} = \sqrt{\frac{2(5.471\times10^{-13}\text{ J})}{3.344\times10^{-27}\text{ kg}}} = 1.81\times10^{7}\text{ m/s}.$$

EVALUATE: $v/c = 0.06$, so it is ok to use the nonrelativistic expression for kinetic energy.

44.10. **IDENTIFY:** We are dealing with the magnetic force on a positron.

SET UP and **EXECUTE:** We want the momentum of the positron. Solve $R = mv/|q|B$ for p, which gives $p = ReB = (0.15\text{ m})e(0.40\text{ T}) = 9.60\times10^{-21}\text{ kg}\cdot\text{m/s}.$

EVALUATE: To check if this positron is relativistic, use $p = mv$ to find its speed, which gives $v = p/m$. Using the momentum we just found gives $v = 1.05\times10^{10}$ m/s which is 300 times the speed of light! So we would need to use relativistic momentum to find the speed.

44.11. **IDENTIFY** and **SET UP:** The masses of the target and projectile particles are equal, so we can use the equation $E_a^2 = 2mc^2(E_m + mc^2)$. E_a is specified; solve for the energy E_m of the beam particles.

EXECUTE: **(a)** Solve for E_m: $E_m = \dfrac{E_a^2}{2mc^2} - mc^2.$

The mass for the alpha particle can be calculated by subtracting two electron masses from the ${}^4_2\text{He}$ atomic mass:

$$m = m_\alpha = 4.002603\text{ u} - 2(0.0005486\text{ u}) = 4.001506\text{ u}.$$

Then $mc^2 = (4.001506\text{ u})(931.5\text{ MeV/u}) = 3.727\text{ GeV}.$

$$E_m = \frac{E_a^2}{2mc^2} - mc^2 = \frac{(16.0\text{ GeV})^2}{2(3.727\text{ GeV})} - 3.727\text{ GeV} = 30.6\text{ GeV}.$$

(b) Each beam must have $\frac{1}{2}E_a = 8.0$ GeV.

EVALUATE: For a stationary target the beam energy is nearly twice the available energy. In a colliding beam experiment all the energy is available and each beam needs to have just half the required available energy.

44.12. **IDENTIFY:** We are dealing with a cyclotron that is accelerating protons.
SET UP: The magnetic field is 1.3 T and the radius of the proton path is 11 cm.
EXECUTE: **(a)** We want the maximum kinetic energy. Use Eq. (44.8) with the known quantities.

$$K_{\text{max}} = \frac{q^2B^2R^2}{2m} = \frac{e^2(1.3\text{ T})^2(0.11\text{ m})^2}{2(1.67\times10^{-27}\text{ kg})} = 0.98\text{ MeV}.$$

The proton rest energy is 938 MeV and K_{max} = 0.98 MeV, so it is accurate to use nonrelativistic expressions.
(b) We want the frequency. Using the known quantities gives $f = eB/2\pi m$ = 20 MHz.
EVALUATE: A kinetic energy of 0.98 MeV is *much* less than present-day accelerators can produce.

44.13. **IDENTIFY:** $E = \gamma mc^2$, where $\gamma = \dfrac{1}{\sqrt{1-v^2/c^2}}$. The relativistic formula for the angular frequency is

$$\omega = \frac{|q|B}{m\gamma}.$$

SET UP: A proton has rest energy $mc^2 = 938.3$ MeV.

EXECUTE: **(a)** $\gamma = \dfrac{E}{mc^2} = \dfrac{1000\times10^3\text{ MeV}}{938.3\text{ MeV}} = 1065.8$, so $v = 0.999999559c$.

(b) Nonrelativistic: $\omega = \dfrac{eB}{m} = 3.83\times10^8$ rad/s.

Relativistic: $\omega = \dfrac{eB}{m}\dfrac{1}{\gamma} = 3.59\times10^5$ rad/s.

EVALUATE: The relativistic expression gives a smaller value for ω.

44.14. **IDENTIFY** and **SET UP:** To create the η^0, the minimum available energy must be equal to the rest mass energy of the products, which in this case is the η^0 plus two protons. In a collider, all of the initial energy is available, so the beam energy is the available energy. Use the particle masses from Table 44.3.
EXECUTE: The minimum amount of available energy must be rest mass energy

$$E_a = 2m_p + m_\eta = 2(938.3\text{ MeV}) + 547.3\text{ MeV} = 2420\text{ MeV}.$$

Each incident proton has half of the rest mass energy, or $1210\text{ MeV} = 1.21\text{ GeV}$.

EVALUATE: We would need much more initial energy if one of the initial protons were stationary. The result here (1.21 GeV) is the *minimum* amount of energy needed; the original protons could have more energy and still trigger this reaction.

44.15. **IDENTIFY** and **SET UP:** For the reaction $\text{p} + \text{p} \rightarrow \text{p} + \text{p} + \text{p} + \overline{\text{p}}$, the two incident protons must have enough kinetic energy to produce a p and a $\overline{\text{p}}$, plus any kinetic energy of the products. If they have the minimum kinetic energy, the products are at rest. The proton and antiproton have equal masses. The available energy for two equal-mass particles is $E_a^2 = 2mc^2(E_m + mc^2)$, where $E_m = K + mc^2$.

EXECUTE: **(a)** In a head-on collision with equal speeds, the laboratory frame is the center-of-momentum frame. For the minimum kinetic energy of the incident protons, the products are all at rest. In that case, the incident protons need only enough kinetic energy to produce a proton and an antiproton. Since the incident protons have equal energy, each one must have kinetic energy equal to the rest energy of a proton, which is 938 MeV.

(b) In this case, the target proton is at rest. Since 4 particles are produced, each of mass m, the available energy E_a must be at least equal to $4mc^2$. Therefore $E_a^2 = 2mc^2(E_m + mc^2) = (4mc^2)^2 = 16m^2c^4$, which gives $E_m = 7mc^2$. Using $E_m = K + mc^2$, we get $K = 6mc^2 = 6(938\text{ MeV}) = 5630\text{ MeV}$.

EVALUATE: When the two protons collide head-on with equal speeds, they need only 938 MeV of kinetic energy each, for a total of 1879 MeV. But when the target is stationary, the kinetic energy needed is 5630 MeV, which is 3 times as much as for a head-on collision.

44.16. **IDENTIFY:** This problem deals with the decay of the omega-minus particle.

SET UP: Use masses (expressed in MeV) from Table 44.3.

EXECUTE: **(a)** We want the energy Q that is released in this decay. From Table 44.3 we have the following masses:

$\mathrm{M}_{\Omega^-} = 1672\text{ MeV}$

$\mathrm{M}_{\Xi^-} = 1322\text{ MeV}$

$\mathrm{M}_{\pi^0} = 135.0\text{ MeV}$

$Q = 1672\text{ MeV} – (1321\text{ MeV} + 135.0\text{ MeV}) = 215\text{ MeV}$.

(b) Use the values for B and S from Table 44.3. The initial B is +1 and the final B is +1, so $\Delta B = 0$. The initial S is –3 and the final S is –2, so $\Delta S = +1$.

EVALUATE: $\Delta B = 0$ agrees with conservation of baryon number, but $\Delta S = +1$ violates strangeness conservation, so this decay is not allowed for the strong interaction. The initial and final lepton numbers are both zero, so this decay is allowed through the weak interaction.

44.17. **IDENTIFY:** The kinetic energy comes from the mass decrease.

SET UP: Table 44.3 gives $m(\mathrm{K}^+) = 493.7\text{ MeV}/c^2$, $m(\pi^0) = 135.0\text{ MeV}/c^2$, and $m(\pi^\pm)$ $= 139.6\text{ MeV}/c^2$.

EXECUTE: **(a)** Charge must be conserved, so $\mathrm{K}^+ \to \pi^0 + \pi^+$ is the only possible decay.

(b) The mass decrease is

$m(\mathrm{K}^+) - m(\pi^0) - m(\pi^+) = 493.7\text{ MeV}/c^2 - 135.0\text{ MeV}/c^2 - 139.6\text{ MeV}/c^2$

$= 219.1\text{ MeV}/c^2$. The energy released is 219.1 MeV.

EVALUATE: The π mesons do not share this energy equally since they do not have equal masses.

44.18. **IDENTIFY:** The energy is due to the mass difference.

SET UP: The energy released is the energy equivalent of the mass decrease. From Table 44.3, the μ^- has mass $105.7\text{ MeV}/c^2$ and the e^- has mass $0.511\text{ MeV}/c^2$.

EXECUTE: The mass decrease is $105.7\text{ MeV}/c^2 - 0.511\text{ MeV}/c^2 = 105.2\text{ MeV}/c^2$ and the energy equivalent is 105.2 MeV.

EVALUATE: The electron does not get all of this energy; the neutrinos also get some of it.

44.19. **IDENTIFY:** Table 44.1 gives the mass in units of GeV/c^2. This is the value of mc^2 for the particle.

SET UP: $m(\mathrm{Z}^0) = 91.2\text{ GeV}/c^2$.

EXECUTE: $E = 91.2\times10^9\text{ eV} = 1.461\times10^{-8}\text{ J}$; $m = E/c^2 = 1.63\times10^{-25}\text{ kg}$; $m(\mathrm{Z}^0)/m(\mathrm{p}) = 97.2$

EVALUATE: The rest energy of a proton is 938 MeV; the rest energy of the Z^0 is 97.2 times as great.

44.20. **IDENTIFY:** If the initial and final rest mass energies were equal, there would be no leftover energy for kinetic energy. Therefore the kinetic energy of the products is the difference between the mass energy of the initial particles and the final particles.

SET UP: The difference in mass is $\Delta m = M_{\Omega^-} - m_{\Lambda^0} - m_{\mathrm{K}^-}$.

EXECUTE: Using Table 44.3, the energy difference is
$E = (\Delta m)c^2 = 1672 \text{ MeV} - 1116 \text{ MeV} - 494 \text{ MeV} = 62 \text{ MeV}.$

EVALUATE: There is less rest mass energy after the reaction than before because 62 MeV of the initial energy was converted to kinetic energy of the products.

44.21. **IDENTIFY** and **SET UP:** Find the energy equivalent of the mass decrease.
EXECUTE: The mass decrease is $m(\Sigma^+) - m(\text{p}) - m(\pi^0)$ and the energy released is
$mc^2(\Sigma^+) - mc^2(\text{p}) - mc^2(\pi^0) = 1189 \text{ MeV} - 938.3 \text{ MeV} - 135.0 \text{ MeV} = 116 \text{ MeV}.$ (The mc^2 values for each particle were taken from Table 44.3.)
EVALUATE: The mass of the decay products is less than the mass of the original particle, so the decay is energetically allowed and energy is released.

44.22. **IDENTIFY** and **SET UP:** The p and n have baryon number $+1$ and the antiproton $\overline{\text{p}}$ has baryon number -1. $\text{e}^+, \text{e}^-, \overline{\nu}_e,$ and γ all have baryon number zero. Baryon number is conserved if the total baryon number of the products equals the total baryon number of the reactants.
EXECUTE: **(a)** reactants: $B = 1 + 1 = 2.$ Products: $B = 1 + 0 = 1.$ Not conserved.
(b) reactants: $B = 1 + 1 = 2.$ Products: $B = 0 + 0 = 0.$ Not conserved.
(c) reactants: $B = +1.$ Products: $B = 1 + 0 + 0 = +1.$ Conserved.
(d) reactants: $B = 1 - 1 = 0.$ Products: $B = 0.$ Conserved.
EVALUATE: Even though a reaction obeys conservation of baryon number it may still not occur spontaneously, if it is not energetically allowed or if other conservation laws are violated.

44.23. **IDENTIFY** and **SET UP:** The lepton numbers for the particles are given in Table 44.2.
EXECUTE: **(a)** $\mu^- \to \text{e}^- + \nu_\text{e} + \overline{\nu}_\mu \Rightarrow L_\mu: +1 \neq -1, L_\text{e}: 0 \neq +1 + 1,$ so lepton numbers are not conserved.
(b) $\tau^- \to \text{e}^- + \overline{\nu}_\text{e} + \nu_\tau \Rightarrow L_\text{e}: 0 = +1 - 1;\ L_\tau: +1 = +1,$ so lepton numbers are conserved.
(c) $\pi^+ \to \text{e}^+ + \gamma.$ Lepton numbers are not conserved since just one lepton is produced from zero original leptons.
(d) $\text{n} \to \text{p} + \text{e}^- + \overline{\nu}_\text{e} \Rightarrow L_\text{e}: 0 = +1 - 1,$ so the lepton numbers are conserved.
EVALUATE: The decays where lepton numbers are conserved are among those listed in Tables 44.2 and 44.3.

44.24. **IDENTIFY** and **SET UP:** Compare the sum of the strangeness quantum numbers for the particles on each side of the decay equation. The strangeness quantum numbers for each particle are given in Table 44.3.
EXECUTE: **(a)** $\text{K}^+ \to \mu^+ + \nu_\mu;\ S_{\text{K}^+} = +1, S_{\mu+} = 0, S_{\nu_\mu} = 0.$
$S = 1$ initially; $S = 0$ for the products; S is not conserved.
(b) $\text{n} + \text{K}^+ \to \text{p} + \pi^0;\ S_\text{n} = 0, S_{\text{K}^+} = +1, S_\text{p} = 0, S_{\pi^0} = 0.$
$S = 1$ initially; $S = 0$ for the products; S is not conserved.
(c) $\text{K}^+ + \text{K}^- \to \pi^0 + \pi^0;\ S_{\text{K}^+} = +1;\ S_{\text{K}^-} = -1;\ S_{\pi^0} = 0.$
$S = +1 - 1 = 0$ initially; $S = 0$ for the products; S is conserved.
(d) $\text{p} + \text{K}^- \to \Lambda^0 + \pi^0;\ S_\text{p} = 0, S_{\text{K}^-} = -1, S_{\Lambda^0} = -1, S_{\pi^0} = 0.$
$S = -1$ initially; $S = -1$ for the products; S is conserved.
EVALUATE: Strangeness is not a conserved quantity in weak interactions, and strangeness nonconserving reactions or decays can occur.

44.25. **IDENTIFY** and **SET UP:** Each value for the combination is the sum of the values for each quark. Use Table 44.4.
EXECUTE: **(a)** ***uds:***
$Q = \frac{2}{3}e - \frac{1}{3}e - \frac{1}{3}e = 0$

$B = \frac{1}{3} + \frac{1}{3} + \frac{1}{3} = 1$

$S = 0 + 0 - 1 = -1$

$C = 0 + 0 + 0 = 0$

(b) $\underline{\boldsymbol{c\bar{u}}}$**:**

The values for $\bar{\boldsymbol{u}}$ are the negative for those for $\boldsymbol{u}$.

$Q = \frac{2}{3}e - \frac{2}{3}e = 0$

$B = \frac{1}{3} - \frac{1}{3} = 0$

$S = 0 + 0 = 0$

$C = +1 + 0 = +1$

(c) ***ddd:***

$Q = -\frac{1}{3}e - \frac{1}{3}e - \frac{1}{3}e = -e$

$B = \frac{1}{3} + \frac{1}{3} + \frac{1}{3} = +1$

$S = 0 + 0 + 0 = 0$

$C = 0 + 0 + 0 = 0$

(d) $\underline{\boldsymbol{d\bar{c}}}$**:**

$Q = -\frac{1}{3}e - \frac{2}{3}e = -e$

$B = \frac{1}{3} - \frac{1}{3} = 0$

$S = 0 + 0 = 0$

$C = 0 - 1 = -1$

EVALUATE: The charge, baryon number, strangeness, and charm quantum numbers of a particle are determined by the particle's quark composition.

44.26. IDENTIFY: Quark combination produce various particles.

SET UP: The properties of the quarks are given in Table 44.5. An antiquark has charge and quantum numbers of opposite sign from the corresponding quark.

EXECUTE: (a) $Q/e = \frac{2}{3} + \frac{2}{3} + (-\frac{1}{3}) = +1.$ $B = \frac{1}{3} + \frac{1}{3} + \frac{1}{3} = 1.$ $S = 0 + 0 + (-1) = -1.$ $C = 0 + 0 + 0 = 0.$

(b) $Q/e = \frac{2}{3} + \frac{1}{3} = +1.$ $B = \frac{1}{3} + (-\frac{1}{3}) = 0.$ $S = 0 + 1 = 1.$ $C = 1 + 0 = 1.$

(c) $Q/e = \frac{1}{3} + \frac{1}{3} + (-\frac{2}{3}) = 0.$ $B = -\frac{1}{3} + (-\frac{1}{3}) + (-\frac{1}{3}) = -1.$ $S = 0 + 0 + 0 = 0.$ $C = 0 + 0 + 0 = 0.$

(d) $Q/e = -\frac{2}{3} + (-\frac{1}{3}) = -1.$ $B = -\frac{1}{3} + \frac{1}{3} = 0.$ $S = 0 + 0 = 0.$ $C = -1 + 0 = -1.$

EVALUATE: The charge must always come out to be a whole number.

44.27. IDENTIFY: The charge, baryon number, and strangeness of the particles are the sums of these values for their constituent quarks.

SET UP: The properties of the six quarks are given in Table 44.5.

EXECUTE: (a) $S = 1$ indicates the presence of one $\bar{\boldsymbol{s}}$ antiquark and no ***s*** quark. To have baryon number 0 there can be only one other quark, and to have net charge $+e$ that quark must be a ***u***, and the quark content is $\boldsymbol{u\bar{s}}$.

(b) The particle has an $\bar{\boldsymbol{s}}$ antiquark, and for a baryon number of -1 the particle must consist of three antiquarks. For a net charge of $-e$, the quark content must be $\overline{\boldsymbol{dd}}\,\bar{\boldsymbol{s}}$.

(c) $S = -2$ means that there are two ***s*** quarks, and for baryon number 1 there must be one more quark. For a charge of 0 the third quark must be a ***u*** quark and the quark content is ***uss***.

EVALUATE: The particles with baryon number zero are mesons and consist of a quark-antiquark pair. Particles with baryon number 1 consist of three quarks and are baryons. Particles with baryon number -1 consist of three antiquarks and are antibaryons.

44.28. **IDENTIFY:** The decrease in the rest energy of the particles that exist before and after the decay equals the energy that is released.

SET UP: The upsilon has rest energy 9460 MeV and each tau has rest energy 1777 MeV.

EXECUTE: $(m_\Upsilon - 2m_\tau)c^2 = (9460\text{ MeV} - 2(1777\text{ MeV})) = 5906\text{ MeV}.$

EVALUATE: Over half of the rest energy of the upsilon is released in the decay.

44.29. **IDENTIFY** and **SET UP:** The mass of a proton is 938 MeV/c^2, and the mass of the Higgs boson is 125 GeV/c^2 = 125 ×10^3 MeV/c^2.

EXECUTE: $m_{\text{Higgs}}/m_{\text{p}} = (125\times10^3\text{ MeV}/c^2)/(938\text{ MeV}/c^2) = 133.$

EVALUATE: Since the Higgs particle is 133 times as massive as the proton, it takes a great deal of energy to create one. This is the reason that high-energy particle accelerators are needed to test for the existence of the Higgs boson.

44.30. **(a) IDENTIFY** and **SET UP:** First calculate the speed v. Then use that in Hubble's law to find r.

EXECUTE: $v = \left[\dfrac{(\lambda_0/\lambda_S)^2 - 1}{(\lambda_0/\lambda_S)^2 + 1}\right]c = \left[\dfrac{(658.5\text{ nm}/590\text{ nm})^2 - 1}{(658.5\text{ nm}/590\text{ nm})^2 + 1}\right]c = 0.1094c$

$$v = (0.1094)(2.998\times10^8\text{ m/s}) = 3.28\times10^7\text{ m/s}.\;\; v = rH_0.$$

(b) IDENTIFY and **SET UP:** Use Hubble's law to calculate r.

EXECUTE: $r = \dfrac{v}{H_0} = \dfrac{3.28\times10^4\text{ km/s}}{[(67.3\text{ km/s})/\text{Mpc}](1\text{ Mpc}/3.26\text{ Mly})} = 1590\text{ Mly} = 1.59\times10^9\text{ ly}.$

EVALUATE: The red shift $\lambda_0/\lambda_S - 1$ for this galaxy is 0.116. It is therefore about twice as far from earth as the galaxy in Examples 44.8 and 44.9, that had a red shift of 0.053.

44.31. **(a) IDENTIFY** and **SET UP:** Hubble's law is $v = H_0 r$, with $H_0 = (67.3\text{ km/s})/(\text{Mpc})$. 1 Mpc = 3.26 Mly.

EXECUTE: $r = 5210$ Mly, so

$v = H_0 r = [(67.3\text{ km/s})/\text{Mpc}](1\text{ Mpc}/3.26\text{ Mly})(5210\text{ Mly}) = 1.08\times10^5\text{ km/s} = 1.08\times10^8\text{ m/s}.$

(b) IDENTIFY and **SET UP:** Use v from part (a) in $\lambda_0 = \lambda_S\sqrt{\dfrac{c+v}{c-v}} = \sqrt{\dfrac{1+v/c}{1-v/c}}.$

EXECUTE: $\dfrac{\lambda_0}{\lambda_S} = \sqrt{\dfrac{c+v}{c-v}} = \sqrt{\dfrac{1+v/c}{1-v/c}}.$

$$\frac{v}{c} = \frac{1.08\times10^8\text{ m/s}}{2.998\times10^8\text{ m/s}} = 0.3602,\text{ so } \frac{\lambda_0}{\lambda_S} = \sqrt{\frac{1+0.3602}{1-0.3602}} = 1.46.$$

EVALUATE: The galaxy in Examples 44.8 and 44.9 is 710 Mly away so has a smaller recession speed and redshift than the galaxy in this problem.

44.32. **IDENTIFY:** In Example 44.8, z is defined as $z = \dfrac{\lambda_0 - \lambda_S}{\lambda_S}$. Apply $\lambda_0 = \lambda_S\sqrt{\dfrac{c+v}{c-v}} = \sqrt{\dfrac{1+v/c}{1-v/c}}$ to solve for v. Hubble's law is given by $v = H_0 r$.

SET UP: The Hubble constant has a value of $H_0 = 6.73\times10^4\,\dfrac{\text{m/s}}{\text{Mpc}}.$

EXECUTE: **(a)** $1 + z = 1 + \dfrac{(\lambda_0 - \lambda_S)}{\lambda_S} = \dfrac{\lambda_0}{\lambda_S}$. Now we use $\lambda_0 = \lambda_S\sqrt{\dfrac{c+v}{c-v}} = \sqrt{\dfrac{1+v/c}{1-v/c}}$ to obtain

$$1 + z = \sqrt{\frac{c+v}{c-v}} = \sqrt{\frac{1+v/c}{1-v/c}} = \sqrt{\frac{1+\beta}{1-\beta}}.$$

(b) Solving the above equation for β we obtain $\beta = \dfrac{(1+z)^2 - 1}{(1+z)^2 + 1} = \dfrac{1.7^2 - 1}{1.7^2 + 1} = 0.4859.$ Thus,

$$v = 0.4859c = 1.46 \times 10^8 \text{ m/s}.$$

(c) We can use Hubble's law to find the distance to the given galaxy,

$$r = \frac{v}{H_0} = \frac{(1.46 \times 10^8 \text{ m/s})}{(6.73 \times 10^4 \text{ m/s})/\text{Mpc}} = 2.17 \times 10^3 \text{ Mpc}.$$

EVALUATE: $1 \text{ pc} = 3.26 \text{ ly},$ so the distance in part (c) is 7.07×10^9 ly.

44.33. IDENTIFY: The reaction energy Q is defined in Chapter 43 as $Q = (M_A + M_B - M_C - M_D)c^2$ and is the energy equivalent of the mass change in the reaction. When Q is negative the reaction is endoergic. When Q is positive the reaction is exoergic.
SET UP: Use the particle masses given in Section 43.1. 1 u is equivalent to 931.5 MeV.
EXECUTE: $\Delta m = m_e + m_p - m_n - m_{\nu_e}$ so assuming $m_{\nu_e} \approx 0,$

$\Delta m = 0.0005486 \text{ u} + 1.007276 \text{ u} - 1.008665 \text{ u} = -8.40 \times 10^{-4} \text{ u}$

$\Rightarrow E = (\Delta m)c^2 = (-8.40 \times 10^{-4} \text{ u})(931.5 \text{ MeV/u}) = -0.783 \text{ MeV}$ and is endoergic.

EVALUATE: The energy consumed in the reaction would have to come from the initial kinetic energy of the reactants.

44.34. IDENTIFY: The energy released in the reaction is the energy equivalent of the mass decrease that occurs in the reaction.
SET UP: 1 u is equivalent to 931.5 MeV. The neutral atom masses are given in Table 43.2.
EXECUTE: $3m(^4\text{He}) - m(^{12}\text{C}) = 7.80 \times 10^{-3} \text{ u},$ or 7.27 MeV.

EVALUATE: The neutral atom masses include 6 electrons on each side of the reaction equation. The electron masses cancel and we obtain the same mass change as would be calculated using nuclear masses.

44.35. IDENTIFY: The reaction energy Q is defined in Chapter 43 as $Q = (M_A + M_B - M_C - M_D)c^2$ and is the energy equivalent of the mass change in the reaction. When Q is negative the reaction is endoergic. When Q is positive the reaction is exoergic.
SET UP: 1 u is equivalent to 931.5 MeV. Use the neutral atom masses that are given in Table 43.2.
EXECUTE: $m_{^{12}_{6}\text{C}} + m_{^{4}_{2}\text{He}} - m_{^{16}_{8}\text{O}} = 7.69 \times 10^{-3}\text{u},$ or 7.16 MeV, an exoergic reaction.

EVALUATE: 7.16 MeV of energy is released in the reaction.

44.36. IDENTIFY: We are using Hooke's law to model the strong nuclear force.
SET UP and **EXECUTE:** **(a)** Use Coulomb's law modeling the quarks as a point-like particles each having charge $2e/3$ and separated from each other by $r = 0.5$ fm. This gives

$$F = \frac{1}{4\pi\epsilon_0}\frac{(2e/3)^2}{r^2} \approx 400 \text{ N}.$$

(b) We want the spring constant. $F_{\text{spr}} = ks$, so $k = F_{\text{spr}}/s = (400 \text{ N})/(0.5 \text{ fm}) = 8.2 \times 10^{17} \text{ N/m} \approx 8 \times 10^{17}$ N/m.
(c) Convert k to units of MeV/fm^2.

$$k = 8.2 \times 10^{17} \frac{\text{N}}{\text{m}} = \left(8.2 \times 10^{17} \frac{\text{N} \cdot \text{m}}{\text{m}^2}\right)\left(\frac{\text{J}}{\text{N} \cdot \text{m}}\right)\left(\frac{1 \text{ m}}{10^{15} \text{ fm}}\right)^2\left(\frac{1 \text{ MeV}}{1.6 \times 10^{-13} \text{ J}}\right) = 5.1 \text{ MeV/fm}^2 \approx 5 \text{ MeV/fm}^2.$$

(d) We want the stored energy.

$$U = \frac{1}{2}ks^2 = \frac{1}{2}(5.1 \text{ MeV/fm}^2)(0.5 \text{ fm})^2 = 0.64 \text{ MeV} = 640 \text{ KeV}.$$

(e) We want the energy to produce an up and anti-up pair of quarks. The mass of each up quark is 2.3 MeV/c^2, so to produce a pair we need 4.6 MeV.
(f) We want the distance between the quarks. Use the spring constant from part (c) with the energy from part (e).

$$E = \frac{1}{2}ks^2 \to s = \sqrt{2E/k} = \sqrt{\frac{2(4.6\text{ MeV})}{5.1\text{ MeV/fm}^2}} = 1.3\text{ fm}.$$

EVALUATE: The result in part (f) is comparable to the size of an atomic nucleus, so our model is of some use.

44.37. IDENTIFY: The energy comes from a mass decrease.
SET UP: A charged pion decays into a muon plus a neutrino. The muon in turn decays into an electron or positron plus two neutrinos.
EXECUTE: (a) $\pi^- \to \mu^- + \text{neutrino} \to \text{e}^- + \text{three neutrinos.}$
(b) If we neglect the mass of the neutrinos, the mass decrease is

$$m(\pi^-) - m(\text{e}^-) = 273m_\text{e} - m_\text{e} = 272m_\text{e} = 2.480\times10^{-28}\text{ kg}.$$
$$E = mc^2 = 2.23\times10^{-11}\text{ J} = 139\text{ MeV}.$$

(c) The total energy delivered to the tissue is $(50.0\text{ J/kg})(10.0\times10^{-3}\text{ kg}) = 0.500\text{ J}.$ The number of

$$\pi^-\text{ mesons required is } \frac{0.500\text{ J}}{2.23\times10^{-11}\text{ J}} = 2.24\times10^{10}.$$

(d) The RBE for the electrons that are produced is 1.0, so the equivalent dose is

$$1.0(50.0\text{ Gy}) = 50.0\text{ Sv} = 5.0\times10^3\text{ rem}.$$

EVALUATE: The π are heavier than electrons and therefore behave differently as they hit the tissue.

44.38. IDENTIFY: The initial total energy of the colliding proton and antiproton equals the total energy of the two photons.
SET UP: For a particle with mass, $E = K + mc^2$. For a proton, $m_\text{p}c^2 = 938\text{ MeV}$.
EXECUTE: $K + m_\text{p}c^2 = \dfrac{hc}{\lambda}, K = \dfrac{hc}{\lambda} - m_\text{p}c^2.$ Using λ = 0.720 fm = 0.720 $\times 10^{-15}$ m,
we get K = 784 MeV.
EVALUATE: If the kinetic energies of the colliding particles increase, then the wavelength of each photon decreases.

44.39. IDENTIFY: We are investigating colliding proton beams in the Large Hadron Collider.
SET UP and **EXECUTE: (a)** With one bunch per 25 ns, the number of bunches per second is 1/(25 ns) = 40 million.
(b) The fraction of protons that collide is 20/(115 billion) = 1.7×10^{-10}.
(c) We want the number of collisions that occur each second. Using the given information and the result of part (a) gives (40 million bunches/s)(20 collisions/bunch) = 800 million collisions.
(d) We want the proton density ρ in a bunch, with N protons in a cylinder of length L and radius R.

$$\rho = \frac{N}{\pi R^2 L} = \frac{115\text{ billion}}{\pi(10\ \mu\text{m})^2(0.300\text{ m})} = 1.2\times10^{12}\text{ protons/mm}^3.$$

(e) We want the density of hadrons in ordinary matter. Follow the hint. Mass is 75 kg. The body is a cylinder 30 cm in diameter of length 1.75 m tall. $V = \pi R^2 L = \pi(0.15\text{ m})^2(1.75\text{ m}) = 0.124\text{ m}^3$. The number N of hadrons is $N = (75\text{ kg})/(1.67 \times 10^{-27}\text{ kg}) = 4.5 \times 10^{28}$ hadrons. The density is $\rho = N/V = (4.5 \times 10^{28})/(0.124\text{ m}^3) = 3.6 \times 10^{29}\text{ hadrons/m}^3 \approx 4 \times 10^{20}\text{ hadrons/mm}^3$.
EVALUATE: As a check for part (e) we can use the density of water, which is 1000 kg/m^3. This gives

$$\frac{1000\text{ kg/m}^3}{1.67\times10^{-27}\text{ kg}} \approx 6\times10^{29}\text{ hadrons/m}^3 = 6\times10^{20}\text{ hadrons/mm}^3.$$

This result is quite close to our calculation above. Note that the concentration of hadrons in ordinary matter is around 300 million times as great as in the bunches in the Large Hadron Collider.

44.40. **IDENTIFY:** Apply Eq. (44.9).

SET UP: In Eq. (44.9), $E_a = (m_{\Sigma^0} + m_{K^0})c^2$, and with $M = m_p, m = m_{\pi^-}$ and $E_m = (m_{\pi^-})c^2 + K$,

$$K = \frac{E_a^2 - (m_{\pi^-}c^2)^2 - (m_p c^2)^2}{2m_p c^2} - (m_{\pi^-})c^2.$$

EXECUTE: $K = \dfrac{(1193\text{ MeV} + 497.7\text{ MeV})^2 - (139.6\text{ MeV})^2 - (938.3\text{ MeV})^2}{2(938.3\text{ MeV})} - 139.6\text{ MeV} = 904\text{ MeV}.$

EVALUATE: The increase in rest energy is

$(m_{\Sigma^0} + m_{K^0} - m_{\pi^-} - m_p)c^2 = 1193\text{ MeV} + 497.7\text{ MeV} - 139.6\text{ MeV} - 938.3\text{ MeV} = 613\text{ MeV}.$ The threshold kinetic energy is larger than this because not all the kinetic energy of the beam is available to form new particle states.

44.41. **IDENTIFY:** Baryon number, charge, strangeness, and lepton numbers are all conserved in the reactions.

SET UP: Use Table 44.3 to identify the missing particle, once its properties have been determined.

EXECUTE: **(a)** The baryon number is 0, the charge is $+e$, the strangeness is 1, all lepton numbers are zero, and the particle is K^+.

(b) The baryon number is 0, the charge is $-e$, the strangeness is 0, all lepton numbers are zero, and the particle is π^-.

(c) The baryon number is -1, the charge is 0, the strangeness is zero, all lepton numbers are 0, and the particle is an antineutron.

(d) The baryon number is 0 the charge is $+e$, the strangeness is 0, the muonic lepton number is -1, all other lepton numbers are 0, and the particle is μ^+.

EVALUATE: Rest energy considerations would determine if each reaction is endoergic or exoergic.

44.42. **IDENTIFY:** Charge must be conserved. The energy released equals the decrease in rest energy that occurs in the decay.

SET UP: The rest energies are given in Table 44.3.

EXECUTE: **(a)** The decay products must be neutral, so the only possible combinations are $\pi^0\pi^0\pi^0$ *or* $\pi^0\pi^+\pi^-$.

(b) $m_{n^0} - 3m_{\pi^0} = 142.9\text{ MeV}/c^2$, so the kinetic energy of the π^0 mesons is 142.9 MeV. For the other reaction, $m_{n^0} - m_{\pi^0} - m_{\pi^-} - m_{\pi^+} = 133.7\text{ MeV}$.

EVALUATE: The total momentum of the decay products must be zero. This imposes a correlation between the directions of the velocities of the decay products.

44.43. **IDENTIFY** and **SET UP:** Apply the Heisenberg uncertainty principle in the form $\Delta E \Delta t \approx \hbar/2$. Let ΔE be the energy width and let Δt be the lifetime.

EXECUTE: $\dfrac{\hbar}{2\Delta E} = \dfrac{(1.054\times10^{-34}\text{ J}\cdot\text{s})}{2(4.4\times10^{6}\text{ eV})(1.6\times10^{-19}\text{ J/eV})} = 7.5\times10^{-23}\text{ s}.$

EVALUATE: The shorter the lifetime, the greater the energy width.

44.44. **IDENTIFY:** Apply the Heisenberg uncertainty principle in the form $\Delta E \Delta t \approx \hbar/2$. Let Δt be the mean lifetime.

SET UP: The rest energy of the ψ is 3097 MeV.

EXECUTE: $\Delta t = 7.6\times10^{-21}\text{ s} \Rightarrow \Delta E = \dfrac{\hbar}{2\Delta t} = \dfrac{1.054\times10^{-34}\text{ J}\cdot\text{s}}{2(7.6\times10^{-21}\text{ s})} = 6.93\times10^{-15}\text{ J} = 43\text{ keV}.$

$$\frac{\Delta E}{m_\psi c^2} = \frac{0.043 \text{ MeV}}{3097 \text{ MeV}} = 1.4\times10^{-5}.$$

EVALUATE: The energy width due to the lifetime of the particle is a small fraction of its rest energy.

44.45. **IDENTIFY:** Apply $\left|\frac{dN}{dt}\right| = \lambda N$ to find the number of decays in one year.

SET UP: Water has a molecular mass of 18.0×10^{-3} kg/mol.

EXECUTE: **(a)** The number of protons in a kilogram is

$(1.00 \text{ kg})\left(\frac{6.022\times10^{23} \text{ molecules/mol}}{18.0\times10^{-3} \text{ kg/mol}}\right)(2 \text{ protons/molecule}) = 6.7\times10^{25}$. Note that only the protons in the hydrogen atoms are considered as possible sources of proton decay. The energy per decay is $m_\text{p}c^2 = 938.3 \text{ MeV} = 1.503\times10^{-10}$ J, and so the energy deposited in a year, per kilogram, is

$$(6.7\times10^{25})\left(\frac{\ln 2}{1.0\times10^{18} \text{ y}}\right)(1 \text{ y})(1.50\times10^{-10} \text{ J}) = 7.0\times10^{-3} \text{ Gy} = 0.70 \text{ rad}.$$

(b) For an RBE of unity, the equivalent dose is $(1)(0.70 \text{ rad}) = 0.70$ rem.

EVALUATE: The equivalent dose is much larger than that due to the natural background. It is not feasible for the proton lifetime to be as short as 1.0×10^{18} y.

44.46. **IDENTIFY** and **SET UP:** $\phi \to \text{K}^+ + \text{K}^-$. The total energy released is the energy equivalent of the mass decrease.

EXECUTE: **(a)** The mass decrease is $m(\phi) - m(\text{K}^+) - m(\text{K}^-)$. The energy equivalent of the mass decrease is $mc^2(\phi) - mc^2(\text{K}^+) - mc^2(\text{K}^-)$. The rest mass energy mc^2 for the ϕ meson is given in Problem 44.43, and the values for K^+ and K^- are given in Table 44.3. The energy released then is $1019.4 \text{ MeV} - 2(493.7 \text{ MeV}) = 32.0 \text{ MeV}$. The K^+ gets half this, 16.0 Mev.

EVALUATE: **(b)** Does the decay $\phi \to \text{K}^+ + \text{K}^- + \pi^0$ occur? The energy equivalent of the $\text{K}^+ + \text{K}^- + \pi^0$ mass is $493.7 \text{ MeV} + 493.7 \text{ MeV} + 135.0 \text{ MeV} = 1122 \text{ MeV}$. This is greater than the energy equivalent of the ϕ mass. The mass of the decay products would be greater than the mass of the parent particle; the decay is energetically forbidden.

(c) Does the decay $\phi \to \text{K}^+ + \pi^-$ occur? The reaction $\phi \to \text{K}^+ + \text{K}^-$ is observed. K^+ has strangeness $+1$ and K^- has strangeness -1, so the total strangeness of the decay products is zero. If strangeness must be conserved we deduce that the ϕ particle has strangeness zero. π^- has strangeness 0, so the product $\text{K}^+ + \pi^-$ has strangeness -1. The decay $\phi \to \text{K}^+ + \pi^-$ violates conservation of strangeness. Does the decay $\phi \to K^+ + \mu^-$ occur? μ^- has strangeness 0, so this decay would also violate conservation of strangeness.

44.47. **IDENTIFY:** We are dealing with muons in cosmic rays. The energies involved are much greater than the rest energy of muons, so we must use the relativistic equations.

SET UP and **EXECUTE:** **(a)** We want the muon's speed. First find γ and then use it to find the speed.

$$E = m\gamma c^2 \quad \to \quad 6.000 \text{ GeV} = \gamma\,(105.7 \text{ MeV}) \quad \to \quad \gamma = 56.76443$$

$$v = c\sqrt{1-1/\gamma^2} = c\sqrt{1-1/(56.76443)^2} = 0.99969c = 2.997\times10^8 \text{ m/s}.$$

(b) We want the distance the muon travels in one lifetime. $x = vt = (2.997 \times 10^8 \text{ m/s})(2.197\ \mu\text{s}) = 658.4$ m.

(c) We want the distance to the earth's surface. To the muon, the 15.00 km is Lorentz contracted, so the distance it sees itself traveling is $L = L_0/\gamma$ = (15.00 km)/(56.76443) = 0.264 km = 264 m.
(d) We want the time in the earth's frame. The muon's frame is the proper frame.

$$\Delta t = \gamma \Delta t_0 = (56.76443)(2.197\ \mu\text{s}) = 124.7\ \mu\text{s}.$$

(e) We want the distance traveled as seen from the earth frame. $x = vt = (2.997 \times 10^8\ \text{m/s})(124.7\ \mu\text{s})$ = 37.4 km.
(f) As observed in the earth frame, the muon is created 15.00 km above the surface and travels 37.4 km, so it survives its trip through 15.00 km of atmosphere and travels downward into the surface of the earth. At such high energy, the muon can penetrate deeply into the surface without hitting anything, so the depth it reaches is 37.4 km – 15.00 km = 22.4 km.
EVALUATE: Without relativistic effects we would have far fewer cosmic rays striking the earth's surface.

44.48. **IDENTIFY:** The energy comes from the mass difference.
SET UP: $\Xi^- \to \Lambda^0 + \pi^-$. $p_\Lambda = p_\pi = p$. $E_\Xi = E_\Lambda + E_\pi$. $m_{\Xi^-}c^2 = 1322\ \text{MeV}$. $m_\pi c^2 = 139.6\ \text{MeV}$.

$$m_\Xi c^2 = \sqrt{m_\Lambda^2 c^4 + p^2c^2} + \sqrt{m_\pi^2 c^4 + p^2 c^2}.$$

EXECUTE: **(a)** The total energy released is

$$(m_{\Xi^-} - m_\pi - m_\Lambda)c^2 = 1322\ \text{MeV} - 139.6\ \text{MeV} - 1116\ \text{MeV} = 66.4\ \text{MeV}.$$

(b) $m_\Xi c^2 = \sqrt{m_\Lambda^2 c^4 + p^2c^2} + \sqrt{m_\pi^2 c^4 + p^2 c^2}$. $m_\Xi c^2 - \sqrt{m_\Lambda^2 c^4 + p^2c^2} = \sqrt{m_\pi^2 c^4 + p^2 c^2}$.
Square both sides:

$$m_\Xi^2 c^4 + m_\Lambda^2 c^4 + p^2c^2 - 2m_\Xi c^2 E_\Lambda = m_\pi^2 c^4 + p^2c^2.\ \ E_\Lambda = \frac{m_\Xi^2c^4 + m_\Lambda^2 c^4 - m_\pi^2 c^4}{2m_\Xi c^2}.$$

$$K_\Lambda = \frac{m_\Xi^2c^4 + m_\Lambda^2 c^4 - m_\pi^2 c^4}{2m_\Xi c^2} - m_\Lambda c^2.\ \ E_\pi = E_\Xi - E_\Lambda = m_\Xi c^2 - \frac{m_\Xi^2c^4 + m_\Lambda^2 c^4 - m_\pi^2 c^4}{2m_\Xi c^2}.$$

$$E_\pi = \frac{m_\Xi^2c^4 - m_\Lambda^2 c^4 + m_\pi^2 c^4}{2m_\Xi c^2}.\ \ K_\pi = \frac{m_\Xi^2c^4 - m_\Lambda^2 c^4 + m_\pi^2 c^4}{2m_\Xi c^2} - m_\pi c^2.$$

Putting in numbers gives

$$K_\Lambda = \frac{(1322\ \text{MeV})^2 + (1116\ \text{MeV})^2 - (139.6\ \text{MeV})^2}{2(1322\ \text{MeV})^2} - 1116\ \text{MeV} = 8.7\ \text{MeV (13\% of total)}.$$

$$K_\pi = \frac{(1322\ \text{MeV})^2 - (1116\ \text{MeV})^2 + (139.6\ \text{MeV})^2}{2(1322\ \text{MeV})^2} - 139.6\ \text{MeV} = 57.7\ \text{MeV (87\% of total)}.$$

EVALUATE: The two particles do not have equal kinetic energies because they have different masses.

44.49. **IDENTIFY:** The kinetic energy comes from the mass difference.
SET UP and **EXECUTE:** $K_\Sigma = 180\ \text{MeV}$. $m_\Sigma c^2 = 1197\ \text{MeV}$. $m_\text{n}c^2 = 939.6\ \text{MeV}$. $m_\pi c^2 = 139.6\ \text{MeV}$.
$E_\Sigma = K_\Sigma + m_\Sigma c^2 = 180\ \text{MeV} + 1197\ \text{MeV} = 1377\ \text{MeV}$. Conservation of the x-component of momentum gives $p_\Sigma = p_{\text{n}x}$. Then $p_{\text{n}x}^2 c^2 = p_\Sigma^2 c^2 = E_\Sigma^2 - (m_\Sigma c)^2 = (1377\ \text{MeV})^2 - (1197\ \text{MeV})^2$ $= 4.633 \times 10^5\ (\text{MeV})^2$. Conservation of energy gives $E_\Sigma = E_\pi + E_\text{n}$.
$E_\Sigma = \sqrt{m_\pi^2 c^4 + p_\pi^2 c^2} + \sqrt{m_\text{n}^2 c^4 + p_\text{n}^2 c^2}$. $E_\Sigma - \sqrt{m_\text{n}^2 c^4 + p_\text{n}^2 c^2} = \sqrt{m_\pi^2 c^4 + p_\pi^2 c^2}$. Square both sides:
$E_\Sigma^2 + m_\text{n}^2 c^4 + p_{\text{n}x}^2 c^2 + p_{\text{n}y}^2 c^2 - 2E_\Sigma E_\text{n} = m_\pi^2 c^4 + p_\pi^2 c^2$. $p_\pi = p_{\text{n}y}$, so

$$E_\Sigma^2 + m_\text{n}^2 c^4 + p_{\text{n}x}^2 c^2 - 2E_\Sigma E_\text{n} = m_\pi^2 c^4 \text{ and } E_\text{n} = \frac{E_\Sigma^2 + m_\text{n}^2 c^4 - m_\pi^2 c^4 + p_{\text{n}x}^2 c^2}{2E_\Sigma}.$$

$$E_{\text{n}} = \frac{(1377\text{ MeV})^2 + (939.6\text{ MeV})^2 - (139.6\text{ MeV})^2 + 4.633\times10^5\ (\text{MeV})^2}{2(1377\text{ MeV})} = 1170\text{ MeV}.$$

$$K_{\text{n}} = E_{\text{n}} - m_{\text{n}}c^2 = 1170\text{ MeV} - 939.6\text{ MeV} = 230\text{ MeV}.$$

$$E_{\pi} = E_{\Sigma} - E_{\text{n}} = 1377\text{ MeV} - 1170\text{ MeV} = 207\text{ MeV}.$$

$$K_{\pi} = E_{\pi} - m_{\pi}c^2 = 207\text{ MeV} - 139.6\text{ MeV} = 67\text{ MeV}.$$

$$p_{\text{n}}^2c^2 = E_{\text{n}}^2 - m_{\text{n}}^2c^2 = (1170\text{ MeV})^2 - (939.6\text{ MeV})^2 = 4.861\times10^5\ (\text{MeV})^2.$$

The angle θ the velocity of the neutron makes with the $+x$-axis is given by $\cos\theta = \dfrac{p_{\text{n}x}}{p_{\text{n}}} = \sqrt{\dfrac{4.633\times10^5}{4.861\times10^5}}$ and $\theta = 12.5^{\circ}$ below the $+x$-axis.

EVALUATE: The decay particles do not have equal energy because they have different masses.

44.50. **IDENTIFY:** The kinetic energy comes from the mass difference, and momentum is conserved.

SET UP: $|p_{\pi^+y}| = |p_{\pi^-y}|$. $p_{\pi^+}\sin\theta = p_{\pi^-}\sin\theta$ and $p_{\pi^+} = p_{\pi^-} = p_{\pi}$. $m_{\text{K}}c^2 = 497.7\text{ MeV}$.

$$m_{\pi}c^2 = 139.6\text{ MeV}.$$

EXECUTE: Conservation of momentum for the decay gives $p_{\text{K}} = 2p_{\pi x}$ and $p_{\text{K}}^2 = 4p_{\pi x}^2$.

$p_{\text{K}}^2c^2 = E_{\text{K}}^2 - m_{\text{K}}^2c^2$. $E_K = 497.7\text{ MeV} + 225\text{ MeV} = 722.7\text{ MeV}$, so

$p_{\text{K}}^2c^2 = (722.7\text{ MeV})^2 - (497.7\text{ MeV})^2 = 2.746\times10^5\ (\text{MeV})^2$ and

$p_{\pi x}^2c^2 = [2.746\times10^5\ (\text{MeV})^2]/4 = 6.865\times10^4\ (\text{MeV})^2$. Conservation of energy says $E_{\text{K}} = 2E_{\pi}$.

$E_{\pi} = \dfrac{E_{\text{K}}}{2} = 361.4\text{ MeV}$. $K_{\pi} = E_{\pi} - m_{\pi}c^2 = 361.4\text{ MeV} - 139.6\text{ MeV} = 222\text{ MeV}$.

$p_{\pi}^2c^2 = E_{\pi}^2 - (m_{\pi}c^2)^2 = (361.4\text{ MeV})^2 - (139.6\text{ MeV})^2 = 1.11\times10^5\ (\text{MeV})^2$. The angle θ that the velocity of the π^+ particle makes with the $+x$-axis is given by $\cos\theta = \sqrt{\dfrac{p_{\pi x}^2c^2}{p_{\pi}^2c^2}} = \sqrt{\dfrac{6.865\times10^4}{1.11\times10^5}}$, which gives $\theta = 38.2^{\circ}$.

EVALUATE: The pions have the same energy and go off at the same angle because they have equal masses.

44.51. **IDENTIFY** and **SET UP:** For nonrelativistic motion, the maximum kinetic energy in a cyclotron is $K_{\max} = \dfrac{q^2R^2}{2m}B^2$. The angular frequency is $\omega = |q|B/m$.

EXECUTE: **(a)** The rest energy of a proton is 938 MeV, and the kinetic energies in the data table in the problem are around 1 MeV or less, so there is no need to use relativistic expressions.

(b) Figure 44.51 shows the graph of $K_{\max}$ versus B^2 for the data in the problem. The graph is clearly a straight line and has slope equal to 6.748 MeV/T^2 = 1.081 $\times10^{-12}$ J/T^2. The formula for $K_{\max}$ is $K_{\max} = \dfrac{q^2R^2}{2m}B^2$, so a graph of $K_{\max}$ versus B^2 should be a straight line with slope equal to $q^2R^2/2m$.

Solving $q^2R^2/2m$ = slope for R gives

$$R = \sqrt{\frac{2m(\text{slope})}{q^2}} = \sqrt{\frac{2(1.673\times10^{-27}\text{ kg})(1.081\times10^{-12}\text{ J/T}^2)}{(1.602\times10^{-19}\text{ C})^2}} = 0.375\text{ m} = 37.5\text{ cm}.$$

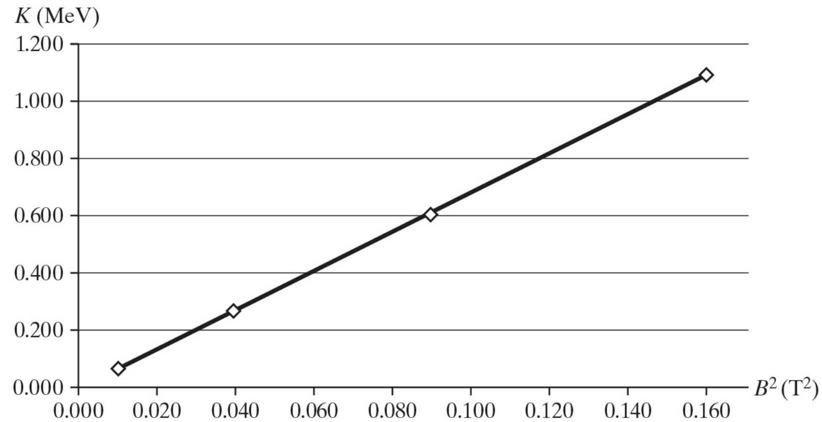

Figure 44.51

(c) Using the result from our graph, we get $K_{max} = (\text{slope})B^2 = (6.748\ \text{MeV/T}^2)(0.25\ \text{T})^2 = 0.42\ \text{MeV}$.
(d) The angular speed is $\omega = |q|B/m = (1.602\times10^{-19}\ \text{C})(0.40\ \text{T})/(1.67\times10^{-27}\ \text{kg}) = 3.8\times10^7$ rad/s.

EVALUATE: In part (c) we can check by using $K_{max} = q^2R^2B^2/2m = (qRB)^2/2m$. Using $B = 0.25$ T and the standard values for the other quantities gives $K_{max} = 6.75\times10^{-14}\ \text{J} = 0.42$ MeV, which agrees with our result.

44.52. **IDENTIFY:** Use Table 44.3 for data on the given particles. Apply conservation of energy in part (b).
SET UP: For any decay, conservation of energy tells us that $E_i = E_f$. If the decaying particle is at rest (or in its rest frame), this gives $m_i c^2 = m_{products}c^2 + K$.
EXECUTE: **(a)** The masses from Table 44.3 are:
Σ^-: 1197 MeV/c^2
Ξ^0: 1315 MeV/c^2
Δ^{++}: 1232 MeV/c^2
Ω^-: 1672 MeV/c^2
We see that Ω^- has the largest mass and Σ^- has the smallest mass.
(b) Solving $m_i c^2 = m_{products}c^2 + K$ for K gives $K = (m_i - m_{products})c^2$. Therefore the greater the difference between the mass of the decaying particle and the mass of decay products, the greater the kinetic energy. We show the decays and the mass differences below.
$\Sigma^- \to n + \pi^-$: $K = (1197 - 939.6 - 139.6)\ \text{MeV}/c^2 = 117.8\ \text{MeV}/c^2$
$\Xi^0 \to \Lambda^0 + \pi^0$: $K = (1315 - 1116 - 135)\ \text{MeV}/c^2 = 64\ \text{MeV}/c^2$
$\Delta^{++} \to p + \pi^+$: $K = (1232 - 938.3 - 139.6)\ \text{MeV}/c^2 = 154.1\ \text{MeV}/c^2$
$\Omega^- \to \Lambda^0 + K^-$: $K = (1672 - 1116 - 493.7)\ \text{MeV}/c^2 = 62.3\ \text{MeV}/c^2$
The kinetic energy is largest for the Δ^{++} decay and smallest for the Ω^- decay.
EVALUATE: A large-mass particle does not necessarily result in the release of more kinetic energy. For example, the Ω^- particle has more mass than the Δ^{++}, yet the decay products of the Ω^- have less kinetic energy than those of the Δ^{++} decay.

44.53. **IDENTIFY** and **SET UP:** Construct the diagram as specified in the problem. In part (b), use quark charges $\boldsymbol{u} = +\frac{2}{3}, \boldsymbol{d} = \frac{-1}{3}$, and $\boldsymbol{s} = \frac{-1}{3}$ as a guide.

EXECUTE: **(a)** The diagram is given in Figure 44.53. The Ω^- particle has $Q = -1$ (as its label suggests) and $S = -3$. Its appears as a "hole" in an otherwise regular lattice in the $S - Q$ plane.
(b) The quark composition of each particle is shown in the figure.

EVALUATE: The mass difference between each S row is around 145 MeV (or so). This puts the Ω^- mass at about the right spot. As it turns out, all the other particles on this lattice had been discovered already and it was this "hole" and mass regularity that led to an accurate prediction of the properties of the Ω^-!

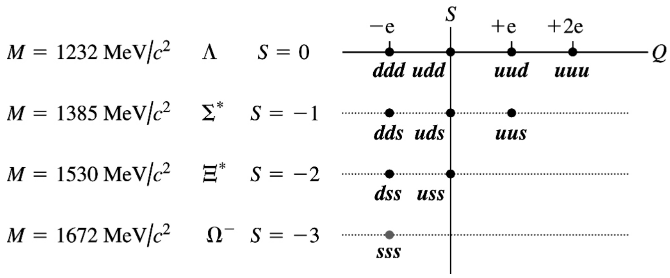

Figure 44.53

44.54. **IDENTIFY:** This problem deals with the decay of a kaon, K^+.
SET UP: We use relativistic equations and treat the neutrino as massless. The structure and decay of a K^+ are $K^+ = u\bar{d}$, $K^+ \to \bar{\mu}^+ + \nu_\mu$.

EXECUTE: **(a)** Energy conservation: $M_K c^2 = \gamma M_\mu c^2 + E_\nu$.

(b) Momentum conservation: The initial momentum is zero. The neutrino is treated as massless, so $p_\nu = E_\nu/c$. Momentum conservation gives $\gamma M_\mu v = E_\nu/c$.

(c) We want the speed of the muon. Combine the energy and momentum equations from (a) and (b). This leads to $M_K c^2 = \gamma M_\mu c^2 + \gamma M_\mu vc$.

Next substitute for σ and then for γ, and finally solve for v.

$$\sigma = \gamma(1 + v/c)$$

$$\sigma = \frac{1}{\sqrt{1 - v^2/c^2}}(1 + v/c)$$

$$v = c\frac{\sigma^2 - 1}{\sigma^2 + 1}.$$

(d) $\sigma = M_K/M_\mu = (493.7\ \text{MeV}/c^2)/(105.7\ \text{MeV}/c^2) = 4.671$.
(e) We want E_μ. First use the results of (c) and (d) to find v. $v = c(4.671^2 - 1)/(4.671^2 + 1) = 0.91234c$. Now use this result to find γ, giving $\gamma = 2.4424$. Now use $E_\mu = \gamma M_\mu c^2$ to find E_μ.
$E_\mu = (2.4424)(105.7\ \text{MeV}/c^2)c^2 = 258.2$ MeV.
(f) We want the energy of the neutrino. Combine $\gamma M_\mu v = E_\nu/c$ from part (b) and $v/c = 0.91234$ from part (e). This gives $E_\nu = \gamma M_\mu vc = \gamma M_\mu c^2(v/c) = (258.2\ \text{MeV})(0.91234) = 235.5\ \text{MeV}$.

(g) Adding the energy of the muon and neutrino gives 258.2 MeV + 235.5 MeV = 493.7 MeV, which is the rest energy of the kaon. So the answer is *yes*.
EVALUATE: The result in part (g) is consistent with the conservation of energy.

44.55. **IDENTIFY:** We are dealing with an expanding curved space.
SET UP: Follow the directions with each part.
EXECUTE: **(a)** We want D. If θ is in radians, then $D = R\theta$.
(b) We want V. Use $V = dD/dt$ and the result from part (a).

$$V = \frac{dD}{dt} = \frac{d(R\theta)}{dt} = \theta\frac{dR}{dt} = \frac{D}{R}\frac{dR}{dt}.$$

(c) If $V = BD$, find $B(t)$. Use the result from part (b).

$$V = \frac{D}{R}\frac{dR}{dt} = \frac{1}{R}\frac{dR}{dt}D = BD \rightarrow B = \frac{1}{R}\frac{dR}{dt}.$$

(d) We want B. R is increasing at a constant rate of 1.00 μm/s, so $R = R_0 + v_R t$. At 4 years R = 500.0 m + (1.00 μm/s)(4)(3.156 × 10^7 s) = 626 m.

$$B = \frac{1}{R}\frac{dR}{dt} = \left(\frac{1}{626\text{ m}}\right)(1.00\ \mu\text{m/s}) = 1.60\times10^{-9}\text{ s}^{-1}.$$

(e) We want D. $D = R\theta$ = (626 m)(π/3 rad) = 656 m.

(f) We want the separation speed V. Use the result from part (b).

$$V = \frac{dD}{dt} = \frac{D}{R}\frac{dR}{dt} = \left(\frac{656\text{ m}}{626\text{ m}}\right)(1.00\ \mu\text{m/s}) = 1.05\ \mu\text{m/s}.$$

(g) We want the time to reach Xibalba. In this universe, c = 6.35 μm/s and v_R = 1.00 μm/s. The waves travel along the circular arc, but this arc is increasing in length due to the expansion of space. For an infinitesimal time interval dt, the wave travels through an arc distance cdt and an angle $d\theta = (cdt)/R$. Using $R = R_0 + v_R t$, we have

$$d\theta = \frac{cdt}{R_0 + v_R t}$$

Integrating will give a relationship between θ and t.

$$\theta(t) = \int_0^t \frac{cdt'}{R_0 + v_R t'} = \frac{c}{v_R}\left[\ln(R_0 + v_R t) - \ln R_0\right] = \frac{c}{v_R}\ln\left(1 + \frac{v_R t}{R_0}\right).$$

Now solve for t when $\theta = \pi/3$.

$$t = \frac{R_0}{v_R}\left(e^{\pi v_R/3c} - 1\right).$$

From part (d) we know that when the ripple waves are sent, R = 626 m, so R_0 = 626 m. Putting in the numbers gives

$$t = \left(\frac{626\text{ m}}{1.00\ \mu\text{m/s}}\right)\left[e^{\pi(1.00\ \mu\text{m/s})[3(6.35\ \mu\text{m/s})]} - 1\right] = 1.122\times10^8\text{ s} = 3.56\text{ y}.$$

(h) We want the wavelength that the Xibalbans observe. Use Eq. (44.16) with v = 1.05 μm/s at the instant the ripple waves are sent, from part (f).

$$\lambda_0 = \lambda_s\sqrt{\frac{c+v}{c-v}} = (1.00\text{ nm})\sqrt{\frac{(6.35+1.05)\ \mu\text{m/s}}{(6.35+1.05)\ \mu\text{m/s}}} = 1.18\text{ nm}.$$

EVALUATE: The received wavelength is longer than the emitted wavelength. This result is reasonable because this “universe” is expanding.

44.56. **IDENTIFY:** Follow the steps specified in the problem. The Lorentz velocity transformation is given by

$$v_x = \frac{v_x' + u}{1 + uv_x'/c^2}.$$

SET UP: Let the +x-direction be the direction of the initial velocity of the bombarding particle.

EXECUTE: **(a)** For mass m, in $v_x = \dfrac{v_x' + u}{1 + uv_x'/c^2}$, $u = -v_{\text{cm}}$, $v' = v_0$, and so $v_m = \dfrac{v_0 - v_{\text{cm}}}{1 - v_0\, v_{\text{cm}}/c^2}$. For mass M, $u = -v_{\text{cm}}$, $v' = 0$, so $v_M = -v_{\text{cm}}$.

(b) The condition for no net momentum in the center of mass frame is $m\gamma_m v_m + M\gamma_M v_M = 0$, where γ_m and γ_M correspond to the velocities found in part (a). The algebra reduces to

$\beta_m\gamma_m = (\beta_0 - \beta')\gamma_0\gamma_M$, where $\beta_0 = \dfrac{v_0}{c}$, $\beta' = \dfrac{v_{\text{cm}}}{c}$, and the condition for no net momentum becomes

$m(\beta_0 - \beta')\gamma_0\gamma_M = M\beta'\gamma_M$, or $\beta' = \dfrac{\beta_0}{1+\dfrac{M}{m\gamma_0}} = \beta_0\dfrac{m}{m+M\sqrt{1-\beta_0^2}}$. $v_{\text{cm}} = \dfrac{mv_0}{m+M\sqrt{1-(v_0/c)^2}}$.

(c) Substitution of the above expression into the expressions for the velocities found in part (a) gives the relatively simple forms $v_m = v_0\gamma_0\dfrac{M}{m+M\gamma_0}$, $v_M = -v_0\gamma_0\dfrac{m}{m\gamma_0 + M}$. After some more algebra,

$\gamma_m = \dfrac{m+M\gamma_0}{\sqrt{m^2+M^2+2mM\gamma_0}}$, $\gamma_M = \dfrac{M+m\gamma_0}{\sqrt{m^2+M^2+2mM\gamma_0}}$, from which

$m\gamma_m + M\gamma_M = \sqrt{m^2+M^2+2mM\gamma_0}$. This last expression, multiplied by c^2, is the available energy E_a in the center of mass frame, so that

$E_\text{a}^2 = (m^2+M^2+2mM\gamma_0)c^4 = (mc^2)^2 + (Mc^2)^2 + (2Mc^2)(m\gamma_0c^2) = (mc^2)^2 + (Mc^2)^2 + 2Mc^2E_m$, which is Eq. (44.9).

EVALUATE: The energy E_a in the center-of-momentum frame is the energy that is available to form new particle states.

44.57. **IDENTIFY** and **SET UP:** Energy and momentum are conserved.

EXECUTE: The positron is moving slowly, so its only appreciable energy is its rest energy m_ec^2. The total energy released by the annihilation is $2m_ec^2$, but the two photons share it equally to conserve momentum. Therefore they also have equal energy, so each photon has energy m_ec^2, which is choice (d).

EVALUATE: If the positron had significant kinetic energy, the two photons would not have the same momentum and hence would not have the same energy.

44.58. **IDENTIFY** and **SET UP:** One photon travels 3 cm longer than the other one. If $2L$ is the distance between the detectors, one photon travels a distance L + 3 cm and other a distance L – 3 cm. The time for a photon to travel a distance x is $t = x/c$.

EXECUTE: $t_1 = (L + 3\text{ cm})/c$ and $t_2 = (L - 3\text{ cm})/c$. The time interval Δt between the arrival of the two photons is $\Delta t = t_1 - t_2 = (L + 3\text{ cm})/c - (L - 3\text{ cm})/c = (6\text{ cm})/c = (0.06\text{ m})/c = 0.2\times10^{-9}\text{ s} = 0.2\text{ ns}$. This is within the 10-ns window, so the two photons will be counted as simultaneous. Thus choice (d) is correct.

EVALUATE: 0.2 ns is well within the 10-ns window for simultaneity. The annihilation would have to occur over 1.5 m from the center for the photons not to be counted as simultaneous.

44.59. **IDENTIFY** and **SET UP:** The absorption of photons obeys the equation $N = N_0e^{-\mu x}$, where $\mu = 0.1\text{ cm}^{-1}$.

EXECUTE: $N/N_0 = e^{-\mu x} = e^{-(0.1\text{ cm}^{-1})(20\text{ cm})} = 0.14 = 14\%$. Choice (c) is correct.

EVALUATE: If 14% of the photons exit the body, 86% were absorbed within 20 cm of tissue.

CHAPTER 1
UNITS, PHYSICAL QUANTITIES, AND VECTORS

Discussion Questions

Q1.1 One correct experiment can disprove a theory, by showing that it doesn't agree with the outcome of the experiment. Experiments, no matter how many, can never prove a theory to be true. There is always the possibility of the experiment which hasn't been done yet that can show the theory to be wrong. But the more different experiments that agree with a theory, the more plausible and useful the theory is.

Q1.2 This is not possible. You can only take the tangent of an angle, and angles are dimensionless quantities. The tangent is the ratio of two lengths.

Q1.3 My height is 5 ft 6 in. This is 66 inches and equals (66 inches)(2.54 cm/1 in.) = 170 cm. My weight is 180 lbs. This is (180 lbs)(4.448 N/1 lb) = 800 N.

Q1.4 For selling tomatoes this rate of change is insignificant. In ten years the kilogram would increase in mass by 10×10^{-6} g = 1.0×10^{-8} kg. The percentage change in mass is $1.0\times10^{-6}\%$. Scales used for ordinary commerce are much less accurate than this, so the change is not noticeable in these applications. But for very precise scientific work the change could be of significance.

Q1.5 There are many possibilities: the period between rising and setting of the sun, a person's pulse, the time of fall of a rock dropped from a certain height, etc. Some time standards are better than others; a good time standard is stable over time, well defined, and easily reproducible.

Q1.6 Stack 100 sheets, measure the total thickness, and divide by 100.

Q1.7 Other examples are the tangent of an angle, the refractive index of a transparent material, the specific gravity of a liquid, etc.

Q1.8 The SI units of volume are m^3. The quantity $\pi r^3 h$ has dimensions of (length)^4 so can't be a volume.

Q1.9 Moe is precise but not accurate. Joe is accurate but not precise. Flo is accurate and precise. Precise means all arrows hit near to the same spot. Accurate means the arrows hit close to the center of the target.

Q1.10 If $\vec{A}$ is a unit vector, $\vec{A}\bullet\vec{A}=1$. $(\hat{i}+\hat{j}+\hat{k})\bullet(\hat{i}+\hat{j}+\hat{k})=1+1+1=3$, so $(\hat{i}+\hat{j}+\hat{k})$ is not a unit vector. $(\hat{i}+\hat{j}+\hat{k})/\sqrt{3}$ is a unit vector. $(3.0\hat{i}-2.0\hat{j})\bullet(3.0\hat{i}-2.0\hat{j})=9.0+4.0=13.0$, so $(3.0\hat{i}-2.0\hat{j})$ is not a unit vector. $(3.0\hat{i}-2.0\hat{j})/\sqrt{13.0}$ is a unit vector.

Q1.11 Displacement is the distance between the starting point and ending point. When the bicyclist has made a half-circle she is a distance $2R=1000$ m from her starting point, so her displacement is 1000 m, south. When she has made one complete circle she is back to her starting point and her displacement is zero.

Q1.12 It is not possible for two vectors with different length to have a vector sum of zero. The vector sum has its smallest magnitude when the two vectors are antiparallel, and in that case the magnitude of the vector sum is the difference in the lengths of the two vectors, and this is zero only when the two vectors have the same length. If three vectors are to have a vector sum of zero the length of any one can't be greater than the sum of the lengths of the other two.

Q1.13 Time is a scalar, not a vector. The elapsed time is always increasing and always positive and it is completely specified by a single number.

Q1.14 No, a vector includes both magnitude and direction. The instructions only specify direction.

Q1.15 No. The magnitude A of a vector is related to its components A_x and A_y by $A = \sqrt{A_x^2 + A_y^2}$. The only way to have $A = 0$ is for both A_x and A_y to be zero. No. A is greater than either $|A_x|$ or $|A_y|$.

Q1.16 (a) A vector has a positive magnitude and a direction. It does not make sense to say a vector is negative. (b) $\vec{\boldsymbol{B}}$ is the negative of $\vec{\boldsymbol{A}}$ if $\vec{\boldsymbol{B}} + \vec{\boldsymbol{A}} = \mathbf{0}$. Also, $\vec{\boldsymbol{B}}$ is the negative of $\vec{\boldsymbol{A}}$ if $\vec{\boldsymbol{A}}$ and $\vec{\boldsymbol{B}}$ have the same magnitude and opposite directions. This doesn't contradict what was said in part (a).

Q1.17 $C = A + B$ if and only if $\vec{\boldsymbol{A}}$ and $\vec{\boldsymbol{B}}$ are in the same direction. $C = 0$ if and only if either $\vec{\boldsymbol{A}} = \vec{\boldsymbol{B}} = \mathbf{0}$ or $\vec{\boldsymbol{A}}$ and $\vec{\boldsymbol{B}}$ have the same magnitude and are opposite in direction.

Q1.18 No. $\vec{\boldsymbol{A}} \bullet \vec{\boldsymbol{B}} = 0$ only if $\vec{\boldsymbol{A}}$ and $\vec{\boldsymbol{B}}$ are perpendicular. $\vec{\boldsymbol{A}} \times \vec{\boldsymbol{B}} = \mathbf{0}$ only if $\vec{\boldsymbol{A}}$ and $\vec{\boldsymbol{B}}$ are either parallel or antiparallel.

Q1.19 $\vec{\boldsymbol{A}} \bullet \vec{\boldsymbol{A}} = A^2$, the square of the magnitude of $\vec{\boldsymbol{A}}$. $\vec{\boldsymbol{A}} \times \vec{\boldsymbol{A}} = \mathbf{0}$.

Q1.20 The magnitude of $\vec{\boldsymbol{A}}/A$ is $A/A = 1$, so $\vec{\boldsymbol{A}}/A$ is a unit vector. The magnitude A is positive, so $\vec{\boldsymbol{A}}/A$ has the direction of $\vec{\boldsymbol{A}}$. $(\vec{\boldsymbol{A}}/A) \bullet \hat{\boldsymbol{i}} = \cos\theta$.

Q1.21 The percent error is the error divided by the quantity. Therefore, the percent error is $\dfrac{10.0 \text{ m}}{890 \times 10^3 \text{ m}} = 1.1 \times 10^{-3}\ \%$. Since the distance from Berlin to Paris was given as 890 km, the total distance covered should be expressed as 890,000 m. We know the total distance to only two significant figures.

Q1.22 (a) Yes. $\vec{\boldsymbol{A}}$ and $(\vec{\boldsymbol{B}} - \vec{\boldsymbol{C}})$ are each vectors; scalar product of two vectors is legitimate. (b) Yes. $(\vec{\boldsymbol{A}} - \vec{\boldsymbol{B}})$ and $\vec{\boldsymbol{C}}$ are each vectors; vector product of two vectors is legitimate. (c) Yes. $\vec{\boldsymbol{A}}$ and $\vec{\boldsymbol{B}} \times \vec{\boldsymbol{C}}$ are each vectors; scalar product of two vectors is legitimate. (d) Yes. $\vec{\boldsymbol{A}}$ and $\vec{\boldsymbol{B}} \times \vec{\boldsymbol{C}}$ are each vectors; vector product of two vectors is legitimate. (e) No. $\vec{\boldsymbol{B}} \bullet \vec{\boldsymbol{C}}$ is a scalar. The vector product of a vector with a scalar is not defined.

Q1.23 <u>Not Equal</u>: Let $\vec{\boldsymbol{A}} = 2\hat{\boldsymbol{i}}$, $\vec{\boldsymbol{B}} = 4\hat{\boldsymbol{i}}$ and $\vec{\boldsymbol{C}} = 3\hat{\boldsymbol{j}}$. $\vec{\boldsymbol{B}} \times \vec{\boldsymbol{C}} = +12\hat{\boldsymbol{k}}$ and $\vec{\boldsymbol{A}} \times (\vec{\boldsymbol{B}} \times \vec{\boldsymbol{C}}) = -24\hat{\boldsymbol{j}}$. $\vec{\boldsymbol{A}} \times \vec{\boldsymbol{B}} = \mathbf{0}$ so $(\vec{\boldsymbol{A}} \times \vec{\boldsymbol{B}}) \times \vec{\boldsymbol{C}} = \mathbf{0}$.
<u>Equal</u>: Let $\vec{\boldsymbol{A}} = 2\hat{\boldsymbol{i}}$, $\vec{\boldsymbol{B}} = 3\hat{\boldsymbol{j}}$ and $\vec{\boldsymbol{C}} = 4\hat{\boldsymbol{i}}$. $\vec{\boldsymbol{B}} \times \vec{\boldsymbol{C}} = -12\hat{\boldsymbol{k}}$ and $\vec{\boldsymbol{A}} \times (\vec{\boldsymbol{B}} \times \vec{\boldsymbol{C}}) = +24\hat{\boldsymbol{j}}$. $\vec{\boldsymbol{A}} \times \vec{\boldsymbol{B}} = +6\hat{\boldsymbol{k}}$ and $(\vec{\boldsymbol{A}} \times \vec{\boldsymbol{B}}) \times \vec{\boldsymbol{C}} = +24\hat{\boldsymbol{j}}$.

Q1.24 $\vec{\boldsymbol{A}} \times \vec{\boldsymbol{B}}$ is perpendicular to both $\vec{\boldsymbol{A}}$ and $\vec{\boldsymbol{B}}$. If two vectors are perpendicular their scalar product is zero. Since $\vec{\boldsymbol{A}} \times \vec{\boldsymbol{B}}$ is perpendicular to $\vec{\boldsymbol{A}}$, $\vec{\boldsymbol{A}} \bullet (\vec{\boldsymbol{A}} \times \vec{\boldsymbol{B}})$ is zero.

Q1.25 (a) No. $\vec{\boldsymbol{A}} \bullet \vec{\boldsymbol{B}} = AB\cos\phi$. If $\vec{\boldsymbol{A}} \bullet \vec{\boldsymbol{B}} = 0$ it could be that both A and B are nonzero but the angle

ϕ between $\vec{\boldsymbol{A}}$ and $\vec{\boldsymbol{B}}$ is 90°. (b) No. $\left|\vec{\boldsymbol{A}} \times \vec{\boldsymbol{B}}\right| = AB\sin\phi$. If $\left|\vec{\boldsymbol{A}} \times \vec{\boldsymbol{B}}\right| = 0$ it could be that both A and B are nonzero but the angle ϕ between $\vec{\boldsymbol{A}}$ and $\vec{\boldsymbol{B}}$ is either zero or 180°.

Q1.26 $\vec{\boldsymbol{A}}$ **= 0** says that $A = 0$. $A = \sqrt{A_x^2 + A_y^2}$. The only way that A can be zero is for both A_x and A_y to be zero.

CHAPTER 2
MOTION ALONG A STRAIGHT LINE

Discussion Questions

Q2.1 The speedometer measures the magnitude of the instantaneous velocity, the speed. It does not measure velocity because it does not measure direction.

Q2.2 Graph (d) . The dots represent the insect's position as a function of time. If the photographs are taken at equal spaced time intervals, then the displacement in successive intervals is increasing and this means the speed is increasing. Therefore, graphs (a) and (e) can be ruled out. Graph (b) shows decreasing acceleration so would correspond to the speed approaching a constant value, which is not what the photographs show. Graph (c) shows motion in the negative *x*-direction, which is not the case. This leaves graph (d). This graph shows velocity in the positive *x*-direction and increasing speed. This is consistent with the photographs.

Q2.3 The answer to the first question is yes. If the object is initially moving and the acceleration direction is opposite to the velocity direction, then the object slows down, stops for an instant and then starts to move in the opposite direction with increasing speed. An example is an object thrown straight up into the air. Gravity gives the object a constant downward acceleration. The object travels upward, stops at its maximum height and then moves downward. The answer to the second question is no. After the first reversal of the direction of travel the velocity and acceleration are then in the same direction. The object continues moving in the second direction with increasing speed.

Q2.4 Average velocity equals instantaneous velocity when the speed is constant and motion is in a straight line.

Q2.5 a) Yes. For an object to be slowing down, all that is required is that the acceleration be nonzero and for the velocity and acceleration to be in opposite directions. The magnitude of the acceleration determines the rate at which the speed is changing. b) Yes. For an object to be speeding up, all that is required is that the acceleration be nonzero and for the velocity and acceleration to be in the same direction. The magnitude of the acceleration determines the rate at which the speed is changing. But for any nonzero acceleration the speed is increasing when the velocity and acceleration are in the same direction.

Q2.6 Average velocity is the magnitude of the displacement divided by the time interval. Average speed is the distance traveled divided by the time interval. Displacement equals the distance traveled when the motion is in the same direction for the entire time interval, and therefore this is when average velocity equals average speed.

Q2.7 For the same time interval they have displacements of equal magnitude but opposite directions, so their average velocities are in opposite directions. One average velocity vector is the negative of the other.

Q2.8 If in the next time interval the second car had pulled ahead of the first, then the speed of the second car was greater. The second car could also be observed to be alongside a pedestrian standing at the curb, but that does not mean the pedestrian was speeding.

Q2.9 The answer to the first question is no. Average velocity is displacement divided by the time interval. If the displacement is zero, then the average velocity must be zero. The answer to the second question is yes. Zero displacement means the object has returned to its starting point, but its speed at that point need not be zero. See Fig. DQ2.9.

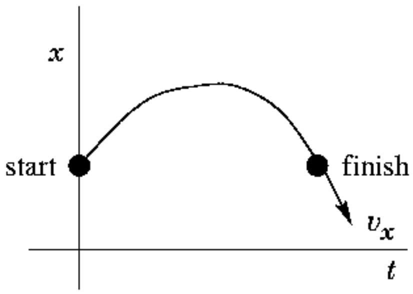

Figure DQ2.9

Q2.10 Zero acceleration means constant velocity, so the velocity could be constant but not zero. See Fig. DQ2.10. An example is a car traveling at constant speed in a straight line.

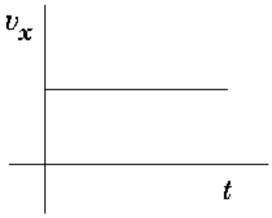

Figure DQ2.10

Q2.11 No. Average acceleration refers to an interval of time and if the velocity is zero throughout that interval, the average acceleration for that time interval is zero. But yes, you can have zero velocity and nonzero acceleration at one instant of time. For example, in Fig. DQ2.11, $v_x = 0$ when the graph crosses the time axis but the acceleration is the nonzero slope of the line. An example is an object thrown straight up into the air. At its maximum height its velocity is zero but its acceleration is g downward.

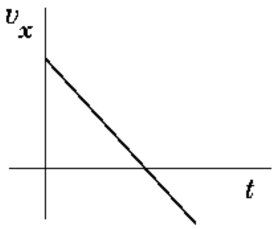

Figure DQ2.11

Q2.12 Yes. When the velocity and acceleration are in opposite directions the object is slowing down.

Q2.13 (a) Two possible *x*-*t* graphs for the motion of the truck are sketched in Fig. DQ2.13.
(b) Yes, the displacement is -258 m and the time interval is 9.0 s, no matter what path the truck takes between x_1 and x_2. The average velocity is the displacement divided by the time interval.

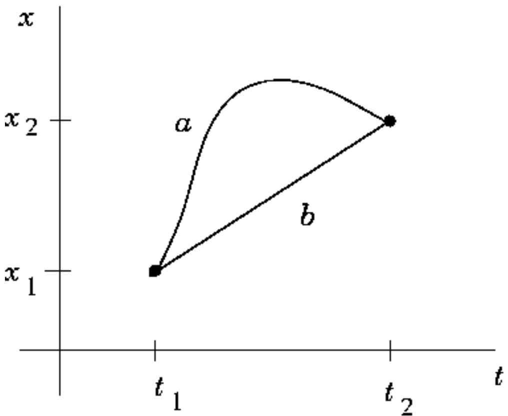

Figure DQ2.13

Q2.14 This is true only when the acceleration is constant. The average velocity is defined to be the displacement divided by the time interval. If the acceleration is not constant, objects can have the same initial and final velocities but different displacements and therefore different average velocities.

Q2.15 It is greater while the ball is being thrown. While being thrown, the ball accelerates from rest to velocity v_{0y} while traveling a distance less than your height. After it leaves your hand, it slows from v_{0y} to zero at the maximum height, while traveling a distance much greater than your height. Eq.(2.13) says that $a_y = \dfrac{v_y^2 - v_{0y}^2}{2(y - y_0)}$. Larger $y - y_0$ means smaller a_y.

Q2.16 (a) Eq.(2.13): $v_y^2 = v_{0y}^2 + 2a_y(y - y_0)$. When an object returns to the release point, $y - y_0 = 0$. Eq.(2.13) then gives $v_y^2 = v_{0y}^2$ and $v_y = \pm v_{0y}$.
(b) $v_y = v_{0y} + a_y t$. At the highest point $v_y = 0$, so $t_{\text{up}} = -v_{0y} / a_y$. At the end of the motion, when the object has returned to the release point, we have shown in (i) that $v_y = -v_{0y}$,
so $t_{\text{total}} = \dfrac{v_y - v_{0y}}{a_y} = \dfrac{-2v_{0y}}{a_y}$ and $t_{\text{total}} = 2t_{\text{up}}$.

Q2.17 The distance between adjacent drops will increase. The drops have the downward acceleration $g = 9.8\text{ m/s}^2$ of a free-falling object. Therefore, their speed is continually increasing and the distance one drop travels in each successive 1.0 s time interval increases. A given drop has fallen for 1.0 s longer than the next drop released after it, so the additional distance it has fallen increases as they fall. Mathematically, let t be the time the second drop has fallen, so the first drop has fallen for time $t + 1.0\text{ s}$. The distance between these two drops then is
$\Delta y = \frac{1}{2}g(t + 1.0\text{ s})^2 - \frac{1}{2}gt^2 = \frac{1}{2}g\left[(2.0\text{ s})t + 1.0\text{ s}^2\right]$. The separation Δy increases as t increases.

Q2.18 Yes. Consider very small time intervals during which the acceleration doesn't have time to change very much, so can be assumed to be constant. Calculate $\Delta v_x = a_x\,\Delta t_1$, for a very small time interval, starting at $t = 0$. Then $v_{1x} = v_{0x} + \Delta v_x$. Since the acceleration is assumed constant for the small time interval, $v_{\text{av},x} = (v_{0x} + v_{1x})/2$ and $\Delta x_1 = v_{\text{av},x}\,\Delta t_1$. Then the position at the end of the interval is $x_1 = x_0 + \Delta x_1$. Repeat the calculation for the next small time interval Δt_2: $\Delta v_x = a_x\,\Delta t_2$, $v_{2x} = v_{1x} + \Delta v_x$, $v_{\text{av},x} = (v_{1x} + v_{2x})/2$, $\Delta x_2 = v_{\text{av},x}\,\Delta t_2$. Repeat for successive small time intervals.

Q2.19 In the absence of air resistance, the first ball rises to its maximum height and then returns to the level of the top of the building. When it returns to the height from which it was thrown, at the top of the building, it is moving downward with speed v_0. The rest of its motion is the same as for the second ball. (a) Since the last part of the motion of the first ball starts with it moving downward with speed v_0 from the top of the building, the two balls have the same speed just before they reach the ground. (b) The second ball reaches the ground first, since the first ball has to move up and then down before repeating the motion of the second ball. (c) Displacement is final position minus initial position. Both balls start at the top of the building and end up at the ground. So they have the same displacement. (d) The first ball has traveled a greater distance.

Q2.20 Let the $+x$-direction be east. The average velocity is the displacement divided by the time interval. The first 120.0 m displacement requires a time of $(120.0 \text{ m/s})/(3.00 \text{ m/s}) = 40.0 \text{ s}$. The second 120.0 m displacement requires a time of $(120.0 \text{ m/s})/(5.00 \text{ m/s}) = 24.0 \text{ s}$. The average velocity is $v_{\text{av-}x} = \dfrac{\Delta x}{\Delta t} = \dfrac{240.0 \text{ m}}{64.0 \text{ s}} = 3.75 \text{ m/s}$. This is less than 4.00 m/s since you spend more time running at 3.00 m/s than at 5.00 m/s.

Q2.21 At the highest point the object instantaneously has zero speed. But its velocity is continually changing, at a constant rate. Acceleration measures the rate of change of velocity. For example, in Fig. 2.25b when the graph crosses the time axis it still has a constant slope that corresponds to the acceleration. Also note the comments in part (d) of the solution to Example 2.7.

Q2.22 For an object released from rest and then moving downward in free-fall, its downward displacement from its initial position of $y_0 = 0$ is given by $y = \frac{1}{2}gt^2$. To increase y by a factor of 3, increase t by a factor of $\sqrt{3}$. You can also see this by letting Y be the original height, so $Y = \frac{1}{2}gT^2$. Let the new height be Y' and the corresponding time be T', so $Y' = \frac{1}{2}g(T')^2$. But $Y' = 3Y = 3\left(\frac{1}{2}gT^2\right)$, so $3\left(\frac{1}{2}gT^2\right) = \frac{1}{2}g(T')^2$ and $T' = \sqrt{3}T$.

CHAPTER 3
MOTION IN TWO OR THREE DIMENSIONS

Discussion Questions

Q3.1 The mass travels in an arc of a circle, so its radial acceleration is $a_{\text{rad}} = v^2 / R$. At the end point its speed is zero so $a_{\text{rad}} = 0$. The tangential component of acceleration causes the speed to change from zero. Therefore, at the ends of the swing the acceleration is tangent to the arc of swing and directed toward the midpoint. At the midpoint the speed of the mass is a maximum. There is a radial acceleration $a_{\text{rad}} = v^2 / R$, directed upward. Since the speed is a maximum, $dv / dt = 0$ and $a_{\tan} = 0$. At the midpoint the acceleration is radially upward. At the end points the acceleration is tangential and at the midpoint it is radial. At points in between both radial and tangential components of the acceleration are nonzero.

Q3.2 See Fig. DQ3.2. There is no component of $\vec{a}$ perpendicular to $\vec{v}$, so the direction of $\vec{v}$ doesn't change and the particle moves in a straight line. Since $\vec{a}$ and $\vec{v}$ are in opposite directions, the speed is decreasing (the particle is slowing down).

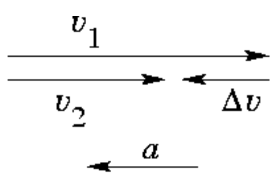

Figure DQ3.2

Q3.3 $\vec{a}$ is always vertically downward and $\vec{v}$ is always tangent to the path. There is no point where $\vec{a}$ and $\vec{v}$ are parallel. At the maximum height $\vec{v}$ is horizontal so that at that point $\vec{a}$ and $\vec{v}$ are perpendicular.

Q3.4 (a) The vertical component of the initial velocity remains zero and the time the book remains in the air is unchanged. The vertical motion is unaffected by the horizontal component of the initial velocity. (b) The horizontal distance the book travels while in the air doubles. The horizontal displacement is $x - x_0 = v_{0x}t$. v_{0x} doubles while t stays the same so $x - x_0$ doubles. (c) The seed of the book just before it reaches the floor is $v = \sqrt{v_x^2 + v_y^2}$. $v_x = v_{0x}$ since $a_x = 0$ so v_x doubles. v_y is unchanged. v increases, but by less than a factor of two.

Q3.5 The downward acceleration due to gravity doesn't depend on the horizontal velocity. Both bullets travel downward the same distance to reach the ground and both initially have zero vertical component of velocity, so both strike the ground at the same time.

Q3.6 After it falls out, the package maintains the horizontal component of velocity that it had while in the plane since it has no horizontal acceleration after it falls out. It accelerates downward due to gravity. Relative to the pilot the package travels straight down. Relative to a person on the ground the package travels both horizontally and vertically; the path relative to this person is a parabola.

Q3.7 The graphs are sketched in Fig. DQ3.7. $a_x = 0$, $a_y = -g$. $x = (v_0 \cos\alpha_0)t$, $v_x = v_x \cos\alpha_0$. $y = (v_0 \sin\alpha_0)t - \frac{1}{2}gt^2$, $v_y = v_0 \sin\alpha_0 - gt$. a_x and a_y are constant. $x(t)$ is a straight line and $y(t)$ is a parabola. v_x is constant and $v_y(t)$ is a straight line.

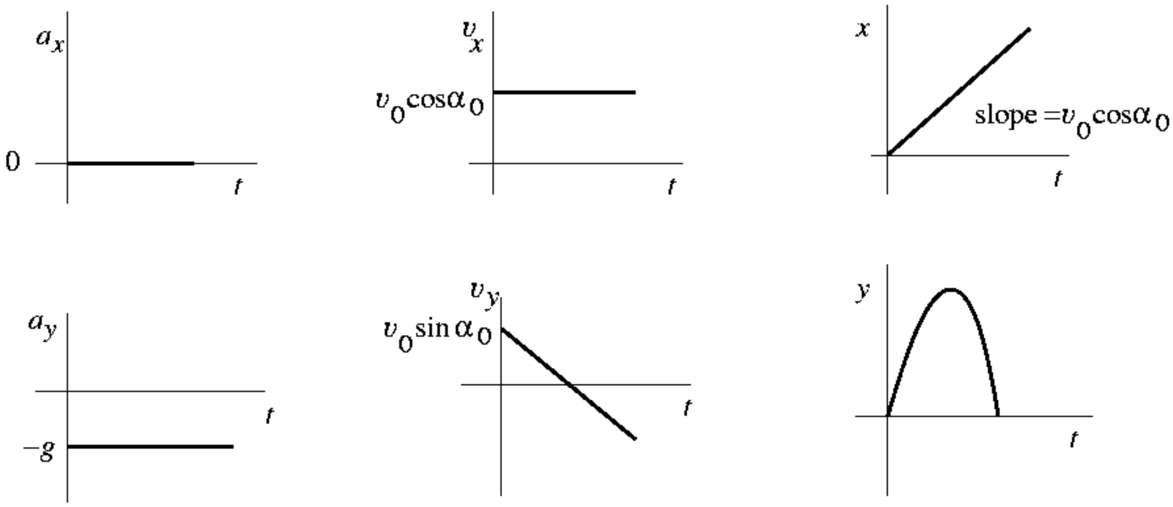

Figure DQ3.7

Q3.8 $R_{\max} = v_0^2 / g$. If the frog jumps straight up $v_{0y} = v_0$ and $h_{\max} = v_0^2 / 2g$ is the maximum height. Therefore $R_{\max} = 2h_{\max}$.

Q3.9 With $+y$ upward the initial velocity has components $v_x = v_0 \cos\theta$ and $v_y = v_0 \sin\theta$. At the maximum height, $v_y = 0$. Since $a_x = 0$, v_x is constant and at the maximum height $v_x = v_0 \cos\theta$. Therefore, at the maximum height the velocity vector is $\vec{\boldsymbol{v}} = (v_0 \cos\theta)\hat{\boldsymbol{i}}$ and the speed is $v = |\vec{\boldsymbol{v}}| = v_0 \cos\theta$. Throughout the motion the acceleration is g, downward, so at the maximum height the acceleration vector is $\vec{\boldsymbol{a}} = -g\hat{\boldsymbol{j}}$.

Q3.10 $\vec{\boldsymbol{v}}_{\text{av}} = \Delta\vec{\boldsymbol{r}} / \Delta t$. For one revolution the object returns to its starting point, so $\Delta\vec{\boldsymbol{r}} = \mathbf{0}$ and $\vec{\boldsymbol{v}}_{\text{av}} = \mathbf{0}$. $\vec{\boldsymbol{a}}_{\text{av}} = \Delta\vec{\boldsymbol{v}} / \Delta t$. After one revolution the velocity vector returns to its initial value so $\Delta\vec{\boldsymbol{v}} = \mathbf{0}$ and $\vec{\boldsymbol{a}}_{\text{av}} = \mathbf{0}$. In circular motion the directions of the velocity and acceleration are continually changing and average to zero over one complete revolution.

Q3.11 $a_{\text{rad}} = v^2 / R$. If the speed v is increased by a factor of 3, the acceleration increases by a factor of $3^2 = 9$. When the radius is decreased by a factor of 2 the acceleration increases by a factor of 2.

Q3.12 In circular motion, uniform or not, the velocity vector is tangent to the circular path. If the speed is not constant the acceleration has a tangential component and the acceleration is not perpendicular to the velocity.

Q3.13 The raindrops fall in the vertical direction relative to the ground. Their velocity relative to the moving car has both vertical and horizontal components and this is the reason for the diagonal streaks on the side window. The diagonal streaks on the windshield arise from a different reason. Air resistance pushes the drops off to one side of the windshield.

Q3.14 Hold the umbrella at an angle, so that the handle is parallel to the motion of the raindrops. This presents the greatest umbrella cross section to the rain.

Q3.15 To cross the river in the shortest time your velocity relative to the earth has the largest possible component perpendicular to the bank. Let S be the swimmer, E be the earth and W be the water.

$\vec{v}_{\text{S/E}} = \vec{v}_{\text{S/W}} + \vec{v}_{\text{W/E}}$. $\vec{v}_{\text{W/E}}$ is parallel to the bank, so $\vec{v}_{\text{S/E}}$ has its largest component perpendicular to the bank when $\vec{v}_{\text{S/W}}$ is in that direction. To cross the river in the shortest time you should head straight across. The current will then carry you downstream, so your path relative to the earth is directed at an angle downstream.

Q3.16 $v_x = v_0 \cos\alpha_0$, where α_0 is the launch angle, is constant throughout the motion, since $a_x = 0$. $|v_y|$ decreases to zero and then starts to increase. The speed is $\sqrt{v_x^2 + v_y^2}$. At $t = 0$, $v = v_0$. At the maximum height the speed has decreased to $v = v_0 \cos\alpha_0$, and then it increases. So, during the motion the speed reaches a minimum at the maximum height, but this minimum speed is not zero. Only graph (d) shows this behavior.

CHAPTER 4
NEWTON'S LAWS OF MOTION

Discussion Questions

Q4.1 No. For an object to be in equilibrium the net force on it must be zero. If there is one and only one non-zero force on the object, the net force isn't zero.

Q4.2 The ball is not in equilibrium. The only force on the ball is gravity. The net force is not zero. The ball has acceleration g downward. The ball has zero velocity at this instant but the velocity will not stay zero.

Q4.3 If the balloon is at rest its acceleration is zero and the net force on it is zero, so it is in equilibrium. The forces on it are the downward force of gravity and the upward buoyant force exerted by the air. These forces must be equal in magnitude, so they add to give zero net force.

Q4.4 The plane has no acceleration. You have the same velocity as the plane.

Q4.5 Let the force applied to each end have magnitude F. For any segment of the rope the force exerted on one end of the segment by the rest of the rope is F; this is what we mean by the tension in the rope.

Q4.6 Before you let go the velocity of the brick is tangent to the circular path. After you let go the only force on the brick is gravity and the brick has downward acceleration g. It has an initial horizontal velocity and travels in projectile motion with a parabolic path.

Q4.7 Newton's 1st law says an object moves with constant velocity unless it is acted on by a nonzero net force. When the car stops suddenly the passengers tend to continue to move with constant velocity, until forces provide an acceleration that stops them. When the car turns, the passengers tend to continue moving in a straight line as the car turns under them.

Q4.8 It is the absence of sufficient force directed opposite to the initial velocity that produces the effect. The passengers continue to move with constant speed until stopped by a force directed backwards. There is no forward force on the passengers.

Q4.9 One possibility is that the bus is accelerating forward so is speeding up, while the ball, with little horizontal force on it continues to move with the initial speed of the bus. Another possibility is that a net force was applied to the ball, for example by someone giving it a push. In the second case the ball was accelerated by the push but after the push is removed it rolls at constant speed relative to the bus. In the first case, so long as the bus is accelerating the ball gains speed relative to the bus. Also, in the first case all objects in the bus would be affected; the passengers would feel an increased horizontal force on them by the seat on which they are sitting as they are accelerated.

Q4.10 $m = F/a$. a has units of length/(time)^2 so m would have units of force$\cdot$(time)^2/length. In the SI system the units would be $\mathrm{N\cdot s^2/m}$.

Q4.11 An accelerating reference frame is an non-inertial frame. The surface of the earth is accelerating. It has $a_{\mathrm{rad}} = v^2/R$ due to the rotation of the earth about its axis and $a_{\mathrm{rad}} = v^2/R$ due to the revolution of the earth about the sun. These accelerations are small, but they prevent the frame of the earth from being precisely an inertial reference frame.

Q4.12 No, in all the cases the van is accelerating and is therefore an non-inertial frame.

Q4.13 This quantity is not a force. It represents the effect on the object of the net force on the object.

Q4.14 The elevator moves at constant speed so is an inertial reference frame. The value $g = 9.8$ m/s^2 is obtained, the same as when the elevator is at rest.

Q4.15 No, in this case the bus has a radial acceleration $a_{\text{rad}} = v^2 / R$. The bus turns while the ball travels in a straight line after it is thrown.

Q4.16 The quantity $g = 9.8\ \text{m/s}^2$ is the acceleration produced by the gravity force when it is the only force on an object. It is not a force, it is the acceleration that results from a force. The units m/s^2 are the units for acceleration, not for force.

Q4.17 The hurt comes from the force the rock exerts on your foot. If your foot is moving at high speed and the rock doesn't move, your foot is stopped over a short distance and its acceleration is large. The large acceleration is produced by a large force between your foot and the rock. But even if the force exerted by the pebble is less, it can be exerted over a smaller area and thus do more damage.

Q4.18 A large force is exerted when the acceleration is large. If the object's speed goes from v_0 to zero over a short distance or during a short time then the acceleration of the object is large.

Q4.19 You have the same speed just before impact in either case. But the distance over which you stop is much smaller for the concrete so your acceleration and the force exerted on you is much larger in that case.

Q4.20 The crumpling increases the stopping distance after impact and decreases the acceleration and therefore the force on the car and passengers. The sides and top don't crumple because they are close to the passengers, who could be crushed.

Q4.21 For a steady pull the acceleration is small and the tension in the string is only slightly greater than the weight of the object. If you jerk the string a large acceleration of the object is produced, until the string breaks. Therefore, in this case the tension in the string is much larger than the weight of the object.

Q4.22 When the crate is either at rest or moving at constant speed its acceleration is zero and the tension in the rope equals the weight of the crate. If the crate is traveling upward and speeding up, its acceleration is upward and the net force is upward; the tension in the rope is greater than the weight of the crate. If the crate is traveling upward and slowing down, its acceleration is downward and the tension is less than the weight.

Q4.23 The gravity force is proportional to the mass, so the gravity force on the 20-kg stone is twice the gravity force on the 10-kg stone. The force is related to the acceleration by $\sum \vec{\boldsymbol{F}} = m\vec{\boldsymbol{a}}$, so $\vec{\boldsymbol{a}} = \sum \vec{\boldsymbol{F}} / m$ and the 20-kg stone requires twice the net force to produce the same acceleration.

Q4.24 A kilogram is a unit of mass and a pound is a unit of force. The correct statement is that at a point where $g = 9.8\ \text{m/s}^2$, a 1.0-kg object has a weight (gravity force) of 2.2 lb.

Q4.25 The motion of an object depends on the forces on that object. The force of the horse on the wagon and the force of the wagon on the horse are a third-law pair and act on different objects.

Q4.26 False. Newton's third law requires that F and P always have equal magnitudes, independent of the other forces on you and the object and independent of any motion you or the object have.

Q4.27 By Newton's 3rd law, $\vec{\boldsymbol{F}}_{\text{T on C}} = -\vec{\boldsymbol{F}}_{\text{C on T}}$; the two forces are equal in magnitude and opposite in direction. This is true no matter how fast each vehicle is moving before the collision.

Q4.28 In both cases, in the absence of air resistance, the only horizontal force is the force that the highway surface applies to the wheels. The highway pushes on the wheels because the wheels push on the highway.

Q4.29 By Newton's 3rd law, the force the car exerts on the van is equal in magnitude and opposite in direction to the force the van exerts on the car. If the vehicles have the same acceleration, the one with the larger mass (the van) has the larger net force on it. In the absence of air resistance the net force on the van is the force exerted by the car. The net force on the car is the force the ground exerts on the car minus the force the van exerts on the car. The force of the ground on the car must be larger than the force of the car on the van.

Q4.30 The free-body force diagram for each person is given in Fig. DQ4.30. The magnitude of the force that *B* exerts on *A* equals the magnitude of the force that *A* exerts on *B*. $F_{\text{g on }A}$ is the magnitude of the force that the ground exerts on *A* and $F_{\text{g on }B}$ is the magnitude of the force that the ground exerts on *B*. The person who wins is the one for whom the ground exerts the larger force. The force of the ground on the person equals in magnitude the force that the person exerts on the ground. So, the winner is the one who exerts the greater horizontal force on the ground.

Figure DQ4.30

Q4.31 Both boxes have the same acceleration a. Treating both objects together as a single object, a force of 100 N gives acceleration a to mass $m_{\text{A}} + m_{\text{B}}$. The force that *A* exerts on *B* gives a smaller mass (m_B) the same acceleration, so this force must be less than 100 N. We can actually calculate this force. Treating both boxes together as a single object, $a = \dfrac{100 \text{ N}}{(150 \text{ N} + 50 \text{ N})/g} = g/2 = 4.9 \text{ m/s}^2$.

For box *B*, $F_{\text{A}} = m_{\text{B}}a = \left(\dfrac{50 \text{ N}}{g}\right)\left(\dfrac{g}{2}\right) = 25 \text{ N}$. By Newton's third law, box *B* pushed to the left on box *A* with force 25 N, so the net force on box *A* is $100 \text{ N} - 25 \text{ N} = 75 \text{ N}$. For box *A*, $ma = (150 \text{ N}/g)(g/2) = 75 \text{ N}$ so Newton's second law is satisfied.

Q4.32 The first statement is correct. The airplane has constant velocity and the net force on it is zero. The second statement is incorrect. When the airplane is either climbing or descending at a steady rate, its velocity is constant, its acceleration is zero, and the net force on it is still zero. In all these situations the net force equals the weight.

Q4.33 This works because of Newton's 1st law. You place the water into motion along with your hands. You suddenly stop or change the direction of motion of your hands and the water continues to move with constant velocity and leaves your hands.

Q4.34 By Newton's 1st law the blood in your head doesn't have sufficient upward force on it to accelerate upward as rapidly as your head. Blood doesn't stay in your head and this causes the sensation.

Q4.35 The person's lower body receives a large forward acceleration due to the force from the car seat in which the person is sitting. The person's head stays at rest until the force from the neck accelerates it to follow the rest of the body. The head lagging behind produces the whiplash.

Q4.36 It is sloppy physics language to say the passenger is "thrown through the windshield." The windshield stops suddenly due to large forces on the car and the passenger continues to move forward.

Q4.37 By Newton's 3rd law the force the large car exerts on the small car equals in magnitude the force the small car exerts on the large car. Equal forces produce unequal accelerations because the masses are different. The small car experiences the greater acceleration. The passengers in the smaller car experience greater accelerations and have larger forces on them.

Q4.38 (i) It is not possible to determine if the rocket is moving at constant velocity. (ii) Perform experiments and see if Newton's 2nd law is obeyed in the frame of the rocket. If the rocket is accelerating Newton's 2nd law won't be obeyed.

CHAPTER 5
APPLYING NEWTON'S LAWS

Discussion Questions

Q5.1 The force diagram for the man plus seat is given in Fig. DQ5.1a. $2T = w_{\text{tot}}$ and therefore $T = w_{\text{tot}}/2$. The tension in the rope is $w_{\text{tot}}/2$, where w_{tot} is the weight of the man plus the weight of the seat. The force diagram for the man is given in Fig. DQ5.1b. $T + n = w_{\text{man}}$ and $n = w_{\text{man}} - T = w_{\text{man}} - w_{\text{tot}}/2 = w_{\text{man}}/2 - w_{\text{seat}}/2$. If the weight of the seat can be neglected compared to the weight of the man, then $T = n = w_{\text{man}}/2$. In this case the tension in the rope and the force of the seat on the man are each half the weight of the man. If the weight of the seat equals the weight of the man, $n = 0$ and $T = w_{\text{man}}$; the seat exerts no force on the man and the tension in the rope equals the weight of the man. If the seat weighs more than the man and the man isn't strapped in, then $T > w_{\text{man}}$ and $n \to 0$. The man accelerates upward and the seat accelerates downward.

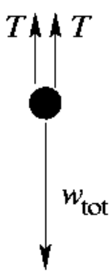

Figure DQ5.1a

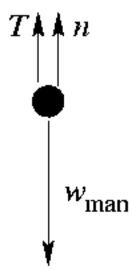

Figure DQ5.1b

Q5.2 (1) If a book sits at rest on a horizontal tabletop the only vertical forces on the book are the upward normal force and the downward weight, and these forces are equal in magnitude. (2) If a crate sits at rest on a ramp that is inclined at an angle α above the horizontal, the normal force is $n = w\cos\alpha$. (3) If a crate sits on a horizontal surface and you push on the book with force P that is at an angle below the horizontal, then $n = w + P\sin\alpha$.

Q5.3 Only the vertical components of the tension at the ends of the rope hold it up; $2T\sin\alpha = w$, where α is the angle of the rope below the horizontal at each support. $T = w/(2\sin\alpha)$. As $\alpha \to 0$, $T \to \infty$.

Q5.4 The force diagram for the car is given in Fig. DQ5.4. w is the weight of the car. This force is vertical. It has a component $w\cos\alpha$ perpendicular to the incline and component $w\sin\alpha$ parallel to the incline. f is the air resistance force exerted by the air on the car. It is directed opposite to the velocity of the car so is parallel to the ground and directed down the hill. The force the ground exerts on the car has two components. The component perpendicular to the ground is the normal force n. The component parallel to the ground is F; the ground pushes on the tires because the tires push on the ground. It is the force F that pushes the car up the hill; the ground pushes the car up the hill.

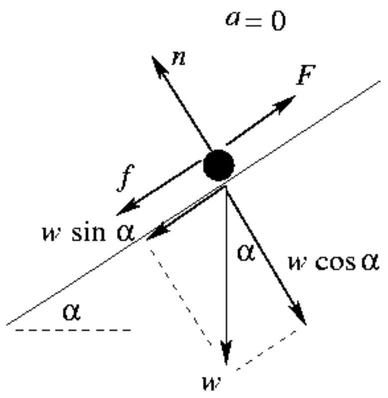

Figure DQ5.4

Q5.5 Use Newton's 2nd law. Apply a known force to the astronaut (for example with a rope attached to a spring balance) and measure his acceleration.

Q5.6 Push parallel to the ramp: The force diagram for the box is given in Fig. DQ5.6a. $P > f + w\sin\alpha$.

Push horizontally: The force diagram for the box is given in Fig. DQ5.6b. $P\cos\alpha > f + w\sin\alpha$.

When you push horizontally only the component of your push parallel to the ramp is effective at moving the box up the ramp. Not only that, but the other component of your push, the component perpendicular to the ramp, increases the normal force which in turn increases the friction force that opposes the motion.

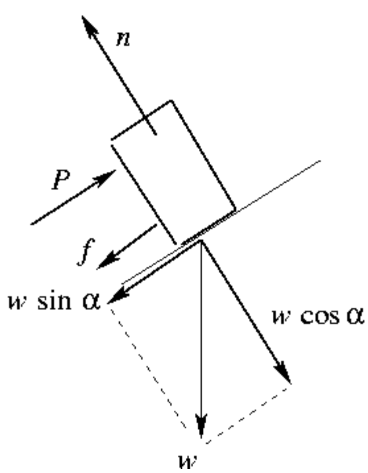

Figure DQ5.6a

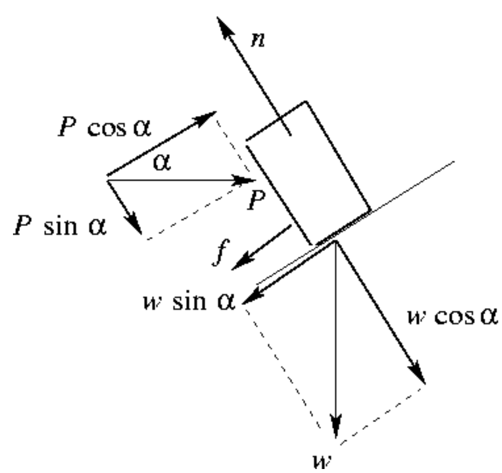

Figure DQ5.6b

Q5.7 When she releases the briefcase, the only force on it is gravity and in the inertial frame of the earth it accelerates downward with $a = g$. If the briefcase isn't moving relative to the elevator, the elevator must also be accelerating downward with acceleration $a = g$.

Q5.8 There is a component $w\sin\alpha$ of the weight of the block that is directed down the incline. To start the block moving down the incline, the force P you apply must satisfy $P + w\sin\alpha > f$ and $P > f - w\sin\alpha$. $w\sin\alpha$ is in the direction of your push and adds to it. To start the block moving up the incline, P must satisfy $P > w\sin\alpha + f$. $w\sin\alpha$ is opposite to your push and subtracts from it. To push the block sideways, it must be that $P > f$. It is easiest to get it moving down the incline and hardest to get it moving up the incline.

Q5.9 Let the crate have mass m and let the ramp be inclined at an angle α above the horizontal. Since the ramp is stationary, the kinetic friction force is always directed opposite to the motion of the crate. When the crate is moving up the ramp, the kinetic friction force f_{k} that the ramp exerts on the crate is directed down the incline and the net force on the crate is $mg\sin\alpha + f_{\mathrm{k}}$, directed down the incline. The acceleration of the crate is $a_{\mathrm{up}} = (mg\sin\alpha + f_{\mathrm{k}})/m$. When the crate is moving down the ramp, the kinetic friction force f_{k} is directed up the incline and the net force on the crate is $mg\sin\alpha - f_{\mathrm{k}}$, directed down the incline. The acceleration of the crate is $a_{\mathrm{down}} = (mg\sin\alpha - f_{\mathrm{k}})/m$. This shows that a_{up} is larger in magnitude than a_{down}. The crate slows down at a greater rate when it is going up the ramp than the rate at which it speeds up when it is coming down the ramp. The result is that the speed of the crate when it returns to the bottom of the ramp is less than the speed it had initially when it started to slide up the ramp. When the crate is going up the component of the gravity force parallel to the ramp and the kinetic friction force are in the same direction and when the crate is coming down they are in opposite directions. The net force on the crate, and hence its acceleration, is greater while it is sliding up than while it is sliding down.

Q5.10 In either case the component of your force F that is horizontal is $F\cos\theta$. But if you pull at an angle above the horizontal your force has an upward component $F\sin\theta$ and the normal force is $n = w - F\sin\theta$. If you push at an angle below the horizontal your force has an downward component $F\sin\theta$ and $n = w + F\sin\theta$. If you pull above the horizontal the normal force is reduced; if you push below the horizontal the normal force is increased. Increasing the normal force increases the friction force that opposes the motion. You exert a smaller force when you pull at an angle above the horizontal.

Q5.11 The friction force is always parallel to the surface that applies it. (a) Can't do. A horizontal friction force in toward the center of the curve is required in order for the car to move in an arc of a circle. (b) Can do. You jump into the air by pushing downward on the floor. (c) Can't do. To start walking requires a horizontal acceleration, which requires a horizontal force. (d) Can do, by pushing upward on the ladder with your feet. But as in (b) it is more difficult without friction, to avoid slipping. (e) Can't do. To change the direction of the car's velocity requires a horizontal friction force exerted by the highway surface on your tires.

Q5.12 The coefficient of kinetic friction is much less than the coefficient of static friction. The maximum static friction force is much larger than the kinetic friction force; once slipping starts the friction force is greatly reduced.

Q5.13 The acceleration of the elevator affects the normal force, and the kinetic friction force that you must push against is proportional to the normal force. When the elevator is accelerating upward, the crate is also accelerating upward and the upward normal force is greater than its weight. When the elevator and crate are accelerating downward, the normal force is less than the weight and when the elevator is traveling at constant speed the normal force equals the weight. The force you must apply is greater when the elevator is accelerating upward and least when it is accelerating downward.

Q5.14 (a) Place a glass of water on a piece of paper. Pull horizontally on the paper so that it accelerates. The friction force that the paper exerts on the glass of water accelerates the glass, causing it to move horizontally along with the paper. (b) Drop a box onto a rapidly moving horizontal conveyor belt. The friction force the belt exerts on the box causes the box to start to move horizontally in the direction the belt is moving. Until the box attains the same speed as the belt it is slipping relative to the belt and the friction is kinetic.

Q5.15 The speed doesn't change because there is no component of net force in the direction of the particle's velocity. The net force and hence the acceleration are perpendicular to the velocity, and this produces a change in the direction of the velocity but not in its magnitude.

Q5.16 $a_{\text{rad}} = v^2 / R$. At 80 km/h the inward horizontal component of the normal force n equals ma_{rad}. At 20 km/h, a_{rad} is significantly less and the inward component of n is much greater than ma_{rad}. The horizontal component of n pushes the car out of its circular path; it slides down the banked roadway and off the road.

Q5.17 The acceleration of the ball is horizontal so in the vertical direction the net force must be zero. The tension in the string must have an upward component to balance the downward gravity force on the ball. Therefore, the string cannot be truly horizontal, it must slope downward below the horizontal as viewed from the center of the circle toward the ball. See Fig. DQ5.17.

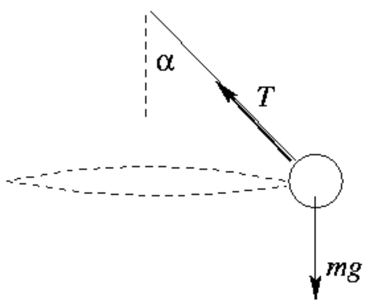

Figure DQ 5.17

Q5.18 There is no such thing as a separate centrifugal force. This is just a name given to the net force, the vector sum of the actual forces, for circular motion.

Q5.19 No. The velocity of the stopper is tangential and the stopper will move in the tangential direction if the horizontal force on it is removed.

Q5.20 At the bottom of the circle, $n = mg + ma_{\text{rad}}$. At the bottom of the circle v is largest and $a_{\text{rad}} = v^2 / R$ can be large. a_{rad} is reduced by increasing R.

Q5.21 With the air removed the ball is in free-fall and has downward displacement $\Delta y = v_{\text{av}-y}\,\Delta t$ in each successive time interval between flashes. Since $v_{\text{av}-y}$ for each time interval increases as the ball speeds up, the displacement of the ball between successive flashes increases. With air resistance the acceleration decreases as the ball falls and gains speed and its displacement between flashes increases less rapidly. If the ball reaches terminal speed, then the distance it travels between flashes becomes constant.

Q5.22 (a) In the absence of air resistance $a_y = -g$ throughout the motion. So, constant acceleration equations apply: $v_y^2 = v_{0y}^2 + 2a_y(y - y_0)$. When $y - y_0 = 0$, $v_y = -v_{0y}$; the speed when it returns is v_0. (b) With air resistance it doesn't go as high and speeds up less rapidly on the way back down, so has speed less than v_0 when it returns.

Q5.23 On the way up, the air resistance force is downward and the acceleration is greater than *g*. On the way down, the air resistance force is upward and the acceleration is less than *g*. The distance up is the same as the distance down, so it takes longer to come down than to go up.

Q5.24 If air resistance is negligible, each ball has the same downward acceleration g and strikes the ground at the same time. With air resistance f, $mg - f = ma_y$. $a_y = g - f/m$ and a_y is less than g. The air resistance force f depends on speed and on size and shape of the object but not on the object's mass. At a given speed f will be the same for both balls but the effect on a_y will be less for the more massive one, the one filled with water. The one filled with water will strike the ground first.

Q5.25 The net downward force on the ball is its weight *mg*, which is constant as the ball falls, minus the upward force due to air resistance. The upward air resistance force increases as the speed of the ball increases as it falls. So, the net downward force decreases and the magnitude of the downward acceleration of the ball decreases as the ball falls. The acceleration steadily decreases, until it becomes zero at the terminal velocity. Graph (d) matches this behavior.

Q5.26 "Dropped from rest" means the initial speed of the ball is zero. The speed of the ball increases until the ball reaches the terminal speed, at which point the speed stays constant. Graph (a) matches this behavior.

Q5.27 There is a horizontal component of air resistance that causes the horizontal component of the velocity to decrease. The ball is traveling with smaller horizontal component of velocity on the way down so travels a shorter horizontal distance.

Q5.28 The only horizontal force on the ball is the horizontal component of the air resistance force. This force is opposite to the horizontal component of the ball's velocity and causes the horizontal component of velocity to decrease. This continues until the horizontal component of velocity is zero and then the horizontal component of air resistance is also zero. The ball reaches its horizontal terminal velocity, which is zero. After the horizontal component of velocity has become zero, the ball moves vertically downward.

CHAPTER 6
WORK AND KINETIC ENERGY

Discussion Questions

Q6.1 No. Whether work is positive or negative does not depend on any choice of coordinates. Work done on an object by a force for a specified displacement of the object is positive if the force has a component in the direction of the displacement. The work is negative if the force has a component opposite to the direction of the displacement of the object.

Q6.2 $W_{\text{tot}} = \Delta K$. At constant speed means $\Delta K = 0$ and $W_{\text{tot}} = 0$. If friction can be neglected, for any upward displacement of the elevator the positive work done by the tension in the cables equals in magnitude the negative work done by gravity.

Q6.3 You must specify the object on which the work is done. W_{tot} in the work-energy theorem is the total work done on the object whose kinetic energy is K. The two forces in a Newton's 3rd law pair do work on different objects.

Q6.4 $W = \frac{1}{2}mv^2$ since the object starts from rest. Let W' and v' be the work and speed when twice the work is done, so $W' = \frac{1}{2}m(v')^2$. $W' = 2W$, so $\frac{1}{2}m(v')^2 = 2\left(\frac{1}{2}mv^2\right)$. This gives $v' = \sqrt{2}v$. The speed increases by a factor of $\sqrt{2}$ when twice the work is done.

Q6.5 Yes. If the net force is always perpendicular to the displacement of the object then the net force doesn't do any work. An example is a block moving in a horizontal circle on the end of a string. If the block moves on a horizontal, frictionless surface, then the net force on the block is the tension in the string. This force is radial and there is no displacement in this direction and the tension does no work on the block. The net force changes the direction of the velocity but doesn't change the speed and the kinetic energy of the object is constant, as the work-energy theorem says it should be when no net work is done.

Q6.6 The tension has the same magnitude at both ends of the rope. The tension does positive work on the cart and negative work on the bucket. The displacements of the cart and bucket have the same magnitude, so the work done on each by the tension has the same magnitude and the total work done by the tension is zero.

Q6.7 There is no work done on the bob. The speed of the bob is constant so its kinetic energy is constant. By the work-energy theorem the total work done on the bob is zero. The tension F is directed along the wire. The bob has no displacement in this direction so this force does no work. The weight mg of the bob is vertically downward. The bob has no displacement in this direction so the gravity force does no work.

Q6.8 In each case the only force that does work on the object is gravity. The work done by gravity is given by $W_{\text{grav}} = mgh$ and this is the same in all three cases. Since the object is released from rest, $W_{\text{grav}} = K_{\text{f}}$, where K_{f} is the kinetic energy the object has at the bottom. (i) In (c) the object has greater mass and hence less speed for the same kinetic energy. Therefore, cases (a) and (b) have the same speed at the bottom and greater speed than case (c). (ii) For all three cases the same amount of work is done.

Q6.9 The force must do both positive and negative work, because for some of the displacement the force is in the $-x$-direction and for some of the displacement the force is in the $+x$-direction. The net work done by $\vec{F}$ is zero if the positive and negative works have the same magnitude. A possible graph of F versus x is sketched in Fig. DQ6.9.

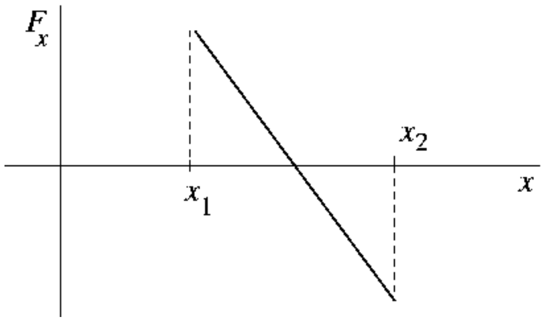

Figure DQ6.9

Q6.10 The change in speed is 5 m/s in both cases, but the kinetic energy depends on v^2 and the change in v^2 is larger for the 15 to 20 m/s speed change.

Q6.11 The direction of the velocity is different for each object; they do not have the same velocity. The speed (the magnitude of the velocity) is the same for all three objects. The kinetic energy depends on the magnitude of the velocity, not on its direction, and the three objects all have the same kinetic energy.

Q6.12 Yes, the total work can be negative. For example, the net force could be opposite to the displacement throughout the motion. An example is the motion of a ball thrown upward. In the absence of air resistance the net force is gravity and is downward. For the motion from just after it leaves the thrower's hand to its maximum height the displacement is upward and the net work done on the ball is negative. No, the negative total work cannot have a magnitude larger than the initial kinetic energy of the object. The work-energy theorem says that $W_{\text{tot}} = K_2 - K_1$. $K_2 = K_1 + W_{\text{tot}}$. If the total work is negative and if its magnitude were larger than K_1,then this equation would say $K_2 < 0$ and this is not possible. For example, consider a net force in a direction opposite to the initial velocity of the object. The force does negative work until it has removed all the kinetic energy of the object and the object is momentarily at rest. After that the object starts moving in the direction of the force and the force starts doing positive work.

Q6.13 $W_{\text{tot}} = K_{\text{final}}$ since $K_{\text{initial}} = 0$. Thus, $W_{\text{tot}} = \frac{1}{2}mv_{\text{final}}^2$. $W_1 = \frac{1}{2}mv_1^2$ and $W_2 = \frac{1}{2}mv_2^2$. If $v_2 = 3v_1$, then $W_2 = 9W_1$. To produce three times the final speed must do nine times the work.

Q6.14 No. In the frame of the driver the truck is already at rest and no work is needed.

Q6.15 (a) There is no vertical displacement of the briefcase so the vertical component of the force your hand exerts does no work. The kinetic energy of the briefcase doesn't change, so in the absence of air resistance there is no horizontal component of the force your hand exerts, and this force does no work. In the presence of air resistance, the force your hand exerts does a small amount of positive work, equal in magnitude to the negative work done by the air resistance force. (b) There is an upward displacement of the briefcase so the upward force your hand exerts does positive work on the briefcase. The positive work done by your hand equals in magnitude the negative work done by gravity, if the initial and final speeds of the briefcase are the same.

Q6.16 Yes, if the displacement of the object is in the direction of the friction force. For a box in the back of an accelerating truck the friction force on the box is the net force that causes the box to accelerate along with the truck (if the box doesn't touch the sides of the truck and if it doesn't slip).

The positive work done by friction equals the increase in kinetic energy of the box.

Q6.17 The work you do is mgh, where m is your mass and h is the vertical height you travel. Your average power is mgh/t ,where t is the time it takes you to run up the stairs. 1 hp = 746 W.

Q6.18 (a) "Strong" indicates the force the person can apply. Power is the rate of doing work. A small force can result in large power if the force is applied to an object that is moving at large speed. (b) The worker must apply a large upward force on the bag equal to the weight of the bag. But this force does no work because the displacement of the bag is horizontal and has no component in the direction of the force.

Q6.19 No. 28,000 hp = (28,000 hp)(746 W/1 hp) = 20.9 MW. The power output (30 MW) would exceed the power input (20.9 MW), and this violates conservation of energy.

Q6.20 $P = Fv = mav$, if the motion is horizontal and if air resistance can be neglected so that the force F supplied by the engine is the net force. As v increases, a decreases; the acceleration is greater at the beginning.

Q6.21 $P = dW/dt$, so $dW = P\,dt$ and the area under the P versus t curve is the work done between t_1 and t_2. $P_{\text{av}} = \Delta W/\Delta t$, so P_{av} is the area divided by $t_2 - t_1$. The graph is given in Fig. DQ6.21 and the calculation is as follows: area = $\frac{1}{2}P_{\text{peak}}(t_2 - t_1)$. P_{av} = area/($t_2 - t_1$). P_{av} = $\frac{1}{2}P_{\text{peak}}$.

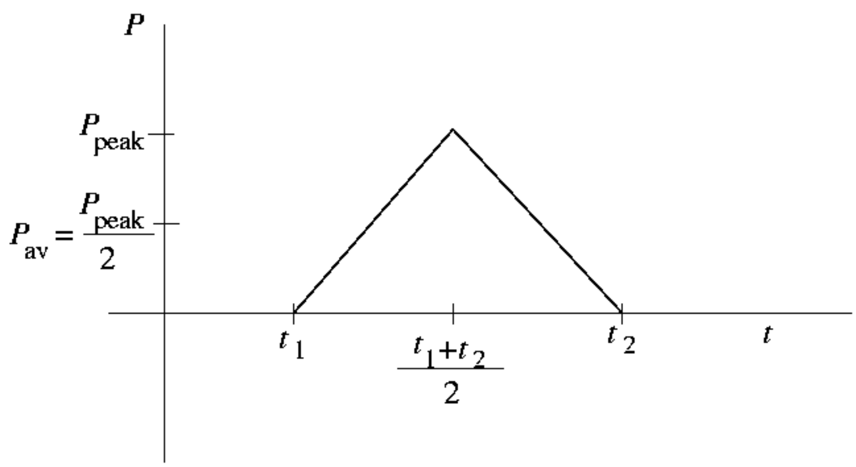

Figure DQ6.21

Q6.22 (a) Yes. If the net force does zero work during a displacement then the particle's speed remains constant. An example is for a particle moving in a circle at constant speed. The net force is radially inward and does no work. (b) No. By $\sum \vec{F} = m\vec{a}$, the net force produces an acceleration and this changes the velocity of the particle. (c) Yes. As reasoned in (a) the speed can remain constant. The kinetic energy depends on the speed of the particle and is independent of the direction of the velocity, so the kinetic energy can remain constant.

Q6.23 $W = \frac{1}{2}kx^2$ and $F = kx$, so $x = \dfrac{F}{k}$ and $W = \dfrac{F^2}{2k}$. If F is doubled then the spring stretches a distance $2x$ and the work done is $4W$.

Q6.24 Let W_1 be the work required to stretch the spring a distance x and let W_2 be the work required to stretch the spring a distance $2x$ from its unstretched length. Then $W_1 = W = \frac{1}{2}kx^2$ and $W_2 = \frac{1}{2}k(2x)^2 = 4W$. The additional work to stretch the spring an additional distance x is $W_2 - W_1 = 4W - W = 3W$.

CHAPTER 7
POTENTIAL ENERGY AND ENERGY CONSERVATION

Discussion Questions

Q7.1 The air resistance force is directed opposite to the motion and hence does negative work W_{other}, both for the upward and downward displacements of the baseball. The ball returns to the same height, so $U_1 = U_2$. $K_2 = K_1 + W_{\text{other}}$; $K_2 < K_1$ since $W_{\text{other}} < 0$.

Q7.2 At the maximum height $K_2 = \frac{1}{2}mv_2^2 = \frac{1}{2}m(v_0 \cos\alpha_0)^2$, where v_0 is the launch speed and α_0 is the launch angle, since at the maximum height $v_y = 0$ and $v_x = v_{0x}$. The smallest α_0 gives the largest v_x and K at the maximum height. $K_1 = K_2 + U_2$ so when K_2 is larger, U_2 and hence y_2 at the maximum height are smaller. That is, for smaller launch angle, the kinetic energy at the maximum height is larger, so by energy conservation the gravitational potential energy must be less. Fig.7.8 shows that smaller α_0 corresponds to smaller maximum height.

Q7.3 No Friction: The kinetic energy at the bottom equals the gravitational potential energy at the top, if the potential energy is taken to be zero at the bottom. The change in gravitational potential energy depends only on the change in height and is independent of the path, so the speed at the bottom does not depend on the shape of the ramp.
Friction: $K_2 = U_1 + W_{\text{f}}$. The speed at the bottom depends on the amount of mechanical energy lost due to the negative work done by friction. The work done by friction depends on the path, so the speed at the bottom depends on the shape of the ramp.

Q7.4 $U = mgy$. The two students assign different values to the initial and final values of the gravitational potential energy but the same value to the change in gravitational potential energy. If the height of the building is h, the student on the roof says $U_1 = 0$, $U_2 = -mgh$ and $\Delta U = U_2 - U_1 = -mgh$. The student on the ground says $U_1 = mgh$, $U_2 = 0$ and $\Delta U = U_2 - U_1 = -mgh$. Conservation of energy, with $K_1 = 0$ and $W_{\text{other}} = 0$, says $K_2 = U_1 - U_2 = -\Delta U$, so the students assign the same value to the kinetic energy of the egg just before it strikes the ground.

Q7.5 In the absence of air resistance and any nonconservative work, $K_1 + U_1 = K_2 + U_2$. When the ball returns to its starting point, $U_1 = U_2$ so $K_2 = K_1$. If the ball leaves his nose with some initial kinetic energy, it has the same amount of kinetic energy when it returns to his nose and it crashes into his face.

Q7.6 To increase the mechanical energy, the total work done by friction would have to be positive. Whether or not this can happen depends on the system. If you set a box on a moving conveyor belt, the friction force on the box does positive work and gives the box kinetic energy. But the friction exerted on the belt by the box does negative work on the belt. By Newton’s 3rd law the friction force exerted by the belt on the box equals the magnitude of the friction force exerted by the box on the belt. If the box doesn’t slip the magnitudes of the displacement of each object are the same and the total work done by friction is zero. If the box slips before reaching the same speed as the belt, the belt travels farther than the box and the total work done is negative. If the box is the system, friction has increased the mechanical energy. If the box and belt are the system, either the mechanical energy of the system has decreased or it has stayed the same. For an isolated system, friction never increases the mechanical energy, it is always a dissipative force.

Q7.7 She does work on the trampoline by pushing against it with her legs. This adds mechanical energy to the system.

Q7.8 A kilowatt is a unit of power. A kilowatt-hour is a unit of energy and electrical energy is what customers are paying for.

Q7.9 (a) The gravity force is downward and the displacement is upward so the gravity force does negative work. $U_{\text{grav}} = mgy$, with $+y$ upward, so the gravitational potential energy of the book increases. When a force does negative work the potential energy associated with that force increases. (b) The gravity force is downward and the displacement is downward so the gravity force does positive work. The gravitational potential energy of the can decreases. When a force does positive work the potential energy associated with that force decreases.

Q7.10 (a) The spring force on the block is directed opposite to the displacement so it does negative work. The potential energy stored in the spring increases. When a force does negative work the potential energy associated with the force increases. (b) The spring force is upward and the block moves upward so the spring force does positive work. The amount the spring is compressed decreases so the potential energy stored in the spring decreases. When a force does positive work the potential energy associated with that force decreases.

Q7.11 (a) $U_{\text{grav}} = mgy$ so the 10.0-kg stone has more gravitational potential energy than the 1.0-kg stone. (b) As they free-fall, the net force on each stone is the stone's weight mg. Newton's second law says $mg = ma$ and $a = g$, the same for each stone. The gravity force on the 10.0-kg stone is larger but more force is required to give it acceleration. (c) Conservation of energy says $mgh = \frac{1}{2}mv^2$, where h is the final height above the ground and v is the speed of the stone just before it strikes the ground. The mass divides out and $v = \sqrt{2gh}$, the same for both stones. They have the same acceleration and they each fall the same distance, so they have the same speed when they reach the ground. (d) The final kinetic energy of the stone equals its gravitational potential energy. The initial gravitational energy is larger for the 10.0 kg stone so the final kinetic energy is larger for this stone. Or, kinetic energy equals $\frac{1}{2}mv^2$. They have equal final speeds so the 10.0 kg stone has larger final kinetic energy.

Q7.12 (a) This is incorrect. (b) This is correct. The object with a smaller mass reaches a greater height. The potential energy stored in the spring does not depend on the mass of the object and is the same for both objects. Conservation of energy says that the final gravitational potential energy equals the initial potential energy stored in the spring so it is the same for both objects. For equal gravitational potential energy mgh the object with the smaller mass must have a greater final height. Conservation of energy says $\frac{1}{2}kx^2 = mgh$ and $h = \dfrac{kx^2}{2mg}$.

Q7.13 The friction force that one hand exerts on the other does work and produces thermal energy.

Q7.14 Gravity is a conservative force. The work done by gravity depends only on the initial and final heights of the object. It is independent of the path and can be expressed in terms of the change in a potential energy function. Friction is a nonconservative force. The work done by friction depends on the path taken between the initial and final positions. The work done by friction therefore cannot be expressed in terms of a change in a potential energy function.

Q7.15 Work done by friction produces thermal energy that is dissipated. Heat engines (Chapter 20) can recover only a portion of the thermal energy for conversion back to mechanical energy.

Q7.16 This is incorrect. It incorrectly gives $\Delta U = U_2 - U_1 = \frac{1}{2}k(x_2 - x_1)^2$ rather than the correct $\Delta U = \frac{1}{2}kx_2^2 - \frac{1}{2}kx_1^2$. The correct form for U is $U = \frac{1}{2}kx^2 + C$, where C is a constant. The student's incorrect choice gives $U = \frac{1}{2}kx^2 + \frac{1}{2}kx_1^2 - kxx_1$. It incorrectly has a linear term in x. The student's incorrect choice gives $F_x = -dU/dx = -k(x - x_1)$, which doesn't give $F_x = 0$ when $x = 0$. If we want $U(x_1) = 0$, then take $U = \frac{1}{2}kx^2 - \frac{1}{2}kx_1^2$. This $U(x)$ gives the correct ΔU and the correct F_x.

Q7.17 If the direction of F_x is reversed then the sign of the work is reversed and $W_{\text{el}} = -(\frac{1}{2}kx_1^2 - \frac{1}{2}kx_2^2)$. $W_{\text{el}} = U_1 - U_2$ so $U = -\frac{1}{2}kx^2$. The graph of this $U(x)$ is given in Fig. DQ7.17. $x = 0$ is a point of unstable equilibrium. Any small displacement away from $x = 0$ produces a force that moves the end of the spring farther from equilibrium.

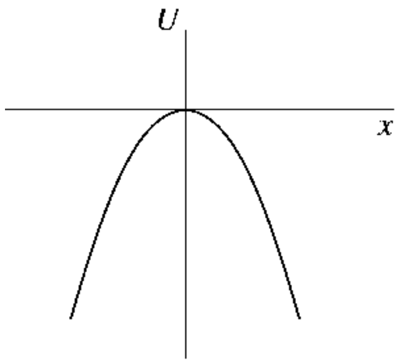

Figure DQ 7.17

Q7.18 The force is always in the $-y$-direction, which is towards the surface of the earth. The force acts to push the system toward lower potential energy and the potential energy is lowered when the object moves toward the earth.

Q7.19 If the particles repel, the force each exerts on the other does negative work when they move closer together and the potential energy increases. If the particles attract, the force each exerts on the other does positive work when they move closer together and the potential energy decreases.

Q7.20 At $x = \pm A$, $E = U$ and $K = 0$. The slope of $U(x)$ is positive at $x = +A$, so at this point $F_x < 0$ and $\vec{F}$ is directed opposite to the displacement. At $x = +A$ the object stops traveling in the $+x$-direction and starts to travel in the $-x$-direction. At $x = -A$, the slope of $U(x)$ is negative so $F_x > 0$ and $\vec{F}$ is directed opposite to the displacement. At $x = -A$ the object stops traveling in the $-x$-direction and starts to travel in the $+x$-direction. At $x = \pm A$ the object "turns around" and starts to head in the opposite direction.

Q7.21 $F_x = -dU/dx$, so $U(x)$ must be constant around a point of neutral equilibrium. The graph of $U(x)$ versus x for a region of neutral equilibrium is given in Fig. DQ7.21. An example is a particle sitting on a horizontal, frictionless surface.

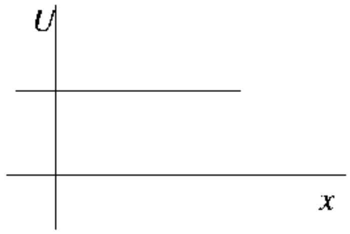

Figure DQ7.21

Q7.22 $E = E_1$: The object moves back and forth between x_a and x_b. Its speed is greatest at $x = x_1$. The graph of $v(x)$ is sketched qualitatively in Fig. DQ7.22a. $E = E_2$: The object moves back and forth between x_c and x_d. It's speed is greatest at x_1. The speed has a local minimum at x_2 and a local maximum at x_3. It's speed at x_3 is slightly less than its speed at x_1. The graph of $v(x)$ is sketched qualitatively in Fig. DQ7.22b.

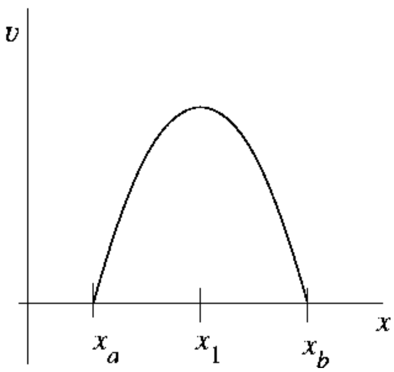

Figure DQ7.22a

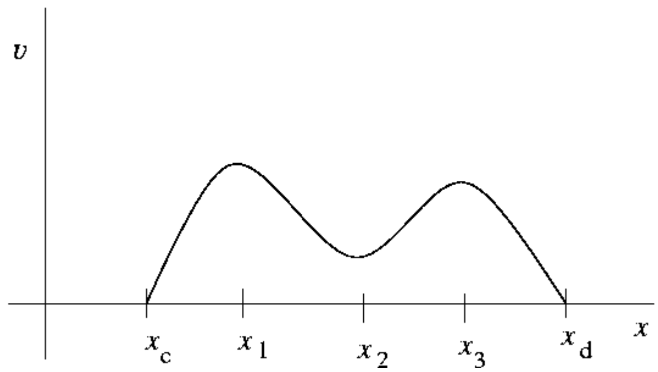

Figure DQ7.22b

Q7.23 $F_x = -dU/dx = -3\alpha x^2$. For any x, $F_x < 0$, so $\vec{F}(x)$ is in the $-x$-direction, for both positive and negative x.

CHAPTER 8
MOMENTUM, IMPULSE, AND COLLISIONS

Discussion Questions

Q8.1 A heavy hammer is more effective. At the same speed the heavy hammer has more momentum and requires more force to stop it.

Q8.2 $K = \frac{1}{2}mv^2 = p^2/2m$. If it has the same momentum, the more massive bowling ball has less kinetic energy. Or, $p = \sqrt{2mK}$ so if they have the same kinetic energy, the bowling ball has more momentum. The momentum of an object determines the force required to stop it, so it would be easier to catch a bowling ball at the same momentum.

Q8.3 For either a raindrop or apple, you can consider the object and earth together as an isolated system and say that the momentum of the object is transferred to the earth. Or, considering only the object as the system you can say that the net external force the ground applies to the object removes its momentum.

Q8.4 Kinetic energy depends only on speed but momentum is a vector and has the same direction as the velocity. The momentum of the car is different in the two cases.

Q8.5 The velocity of the truck relative to the fence post is different from its velocity relative to the police car, so the momentum of the truck is different in these two frames. Both frames are inertial frames so Eq.(8.3) applies and $d\vec{\boldsymbol{p}}/dt$ is the same in both frames.

Q8.6 (a) For a single object $p = mv$ and $K = \frac{1}{2}mv^2$. The kinetic energy is $K = \dfrac{p^2}{2m}$. If $p = 0$ then $K = 0$. (b) The total momentum $\vec{\boldsymbol{P}}$ of the pair of objects is the vector sum of the individual momenta: $\vec{\boldsymbol{P}} = \vec{\boldsymbol{p}}_1 + \vec{\boldsymbol{p}}_2$. The total kinetic energy is the scalar sum $K = K_1 + K_2$. P can be zero without K being zero. An example is two objects that have momenta of equal magnitudes but opposite directions. The vector sum $\vec{\boldsymbol{p}}_1 + \vec{\boldsymbol{p}}_2$ is zero but $\dfrac{p_1^2}{2m} + \dfrac{p_2^2}{2m}$ is not zero. The kinetic energy of an object does not depend on the direction of the velocity and it is never negative. (b) Yes. $K = K_1 + K_2 = \dfrac{p_1^2}{2m} + \dfrac{p_2^2}{2m}$. Both terms are positive so the only way K can be zero is for p_1 and p_2 to both be zero, when both objects are at rest.

Q8.7 Momentum is not conserved, because of the net upward force exerted on the system by the ice as the rock is being thrown. The initial momentum is zero and after the rock is thrown the system has an upward component of momentum. The earth must be included in the system to have an isolated system for which momentum is conserved. There is no external force in the horizontal direction, so the horizontal component of momentum is conserved. The final horizontal component of the total momentum of the system is zero; the woman gains horizontal momentum in one direction and the rock gains an equal magnitude of horizontal momentum in the opposite direction.

Q8.8 Inelastic means $K_2 < K_1$. In a collision of two objects, if they stick together the collision must be inelastic. Such a collision is sometimes called totally inelastic. If the objects don't stick together the forces during the collision can still do nonconservative work and the collision can be inelastic, with $K_2 < K_1$. In Example 8.5, $K_1 = \frac{1}{2}(0.50\text{ kg})(2.0\text{ m/s})^2 + \frac{1}{2}(0.30\text{ kg})(2.0\text{ m/s})^2 = 1.6$ J and $K_2 = \frac{1}{2}(0.50\text{ kg})(0.40\text{ m/s})^2 + \frac{1}{2}(0.30\text{ kg})(2.0\text{ m/s})^2 = 0.64$ J. $K_2 < K_1$ and the collision is inelastic.

Q8.9 The final kinetic energy would be zero if the final speed of the combined object is zero. This will be the case whenever the initial momentum of the system is zero, when $m_A\vec{\boldsymbol{v}}_{A1} + m_B\vec{\boldsymbol{v}}_{B1} = 0$. The initial kinetic energy is $K_1 = K_{A1} + K_{B1} = \frac{1}{2}m_A v_{A1}^2 + \frac{1}{2}m_B v_{B1}^2$ and cannot be zero. In the inelastic collision, momentum is conserved but kinetic energy is not.

Q8.10 The equation $K = p^2/2m$ applies only to each object in the system. The kinetic energy K_{tot} of the system is not equal to $P_{\text{tot}}^2/2m$, where $\vec{\boldsymbol{P}}_{\text{tot}}$ is the total momentum of the system. The vector sum $\vec{\boldsymbol{p}}_A + \vec{\boldsymbol{p}}_B$ can be constant while the scalar sum $p_A^2/2m_A + p_B^2/2m_B$ is not constant.

Q8.11 Define the relative velocity vector to be $\vec{\boldsymbol{v}} = \vec{\boldsymbol{v}}_B - \vec{\boldsymbol{v}}_A$.
Example 8.10: Only the x-components of the velocities are nonzero.
$v_{1x} = v_{B1x} - v_{A1x} = -2.0\,\text{m/s} - 2.0\,\text{m/s} = -4.0\,\text{m/s}$
$v_{2x} = v_{B2x} - v_{A2x} = 3.0\,\text{m/s} - (-1.0\,\text{m/s}) = +4.0\,\text{m/s}$
$\vec{\boldsymbol{v}}_1 = -\vec{\boldsymbol{v}}_2$; the relative velocity vector reverses direction.
Example 8.11: Only the x-components of the velocities are nonzero.
$v_{1x} = v_{B1x} - v_{A1x} = 0 - 2.6\times 10^7\,\text{m/s} = -2.6\times 10^7\,\text{m/s}$
$v_{2x} = v_{B2x} - v_{A2x} = 0.4\times 10^7\,\text{m/s} - (-2.2\times 10^7\,\text{m/s}) = +2.6\times 10^7\,\text{m/s}$
$\vec{\boldsymbol{v}}_1 = -\vec{\boldsymbol{v}}_2$; the relative velocity vector reverses direction.
Example 8.12: Both x-components and y-components of the velocities are nonzero.
$v_{1x} = v_{B1x} - v_{A1x} = 0 - 4.00\,\text{m/s} = -4.00\,\text{m/s}$
$v_{A2x} = v_{A2}\cos\alpha = +1.60\,\text{m/s}$; $\quad v_{B2x} = v_{B2}\cos\beta = +4.00\,\text{m/s}$
$v_{2x} = v_{B2x} - v_{A2x} = 4.00\,\text{m/s} - 1.60\,\text{m/s} = +2.40\,\text{m/s}$
$v_{1y} = v_{B1y} - v_{A1y} = 0$
$v_{A2y} = v_{A2}\sin\alpha = +1.20\,\text{m/s}$; $\quad v_{B2y} = v_{B2}\sin\beta = -2.00\,\text{m/s}$
$v_{2y} = v_{B2y} - v_{A2y} = -2.00\,\text{m/s} - 1.20\,\text{m/s} = -3.20\,\text{m/s}$
$v_1 = \sqrt{v_{1x}^2 + v_{1y}^2} = 4.00$ m/s; $\quad v_2 = \sqrt{v_{2x}^2 + v_{2y}^2} = 4.00$ m/s
The magnitude of the relative velocity, before and after the collision is the same, but in this two-dimensional case the relative velocity vector does not simply reverse direction.

Q8.12 The hard collision with the concrete is of shorter duration so the maximum force is larger.

Q8.13 The Ping-Pong ball gains momentum in the $+x$-direction and the bowling ball loses momentum in the $+x$-direction, so that the total momentum of the system is conserved. Therefore, the bowling ball slows down a little and loses some kinetic energy. Kinetic energy is transferred from the bowling ball to the Ping-Pong ball and the total energy of the two balls is conserved.

Q8.14 The momentum change of the bullets is greater if they bounce off, so the average force on the plate is greater in that case.

Q8.15 For a constant force the change in momentum equals the impulse, the product of force and time. Half the force requires twice the time for the same impulse and momentum change; the 2 N force would need to act for 0.50 s.

Q8.16 There must be times when $\sum F_x$ is positive and times when it is negative. The area under the positive part must equal the area under the negative part, so that the net impulse will be zero.

Q8.17 If the force exerted on the racket by the person's hand while the ball and racket are in contact is neglected then the total momentum of the system is conserved. As the ball moves through the air it is acted on by the external force of gravity and this net external force changes its momentum.

Q8.18 Apply Eq.(8.31). After the rifle is fired,
$v_{\text{cm}x} = (5.00\times10^{-3}\,\text{kg})(300\,\text{m/s}) + (3.00\,\text{kg})(-0.500\,\text{m/s}) = 0$.
The center of mass of the system maintains a constant velocity of zero during the firing. This agrees with Eq.(8.34); the net external force on the system is zero so the velocity of the center of mass is constant.

Q8.19 The momentum of the system egg plus earth remains constant. The egg acquires a downward momentum and the earth acquires an upward momentum of the same magnitude so that the total momentum of the system is zero. The mass of the earth is much, much larger than that of the egg so the upward velocity of the earth is very, very small.

Q8.20 No. With respect to horizontal motion she is an isolated system and her center of mass must remain at rest.

Q8.21 No. For both fragments to fall straight down each fragment would have zero horizontal component of momentum and the total momentum of the system would have zero horizontal component immediately after the explosion. But immediately before the explosion the velocity of the shell is horizontal and the horizontal component of its momentum is not zero. Momentum is conserved in the explosion so the horizontal component of the total momentum can't be zero immediately after the explosion.

Q8.22 By Newton's 3rd law the fragments exert forces of equal magnitudes on each other. By Newton's 2nd law the same force produces a greater acceleration for the lighter fragment. The forces on each fragment act for the same time interval, so with a greater acceleration the lighter fragment acquires a greater final speed. In fact, $v_A / v_B = m_B / m_A$. $K_A / K_B = (m_A / m_B)(v_A / v_B)^2 = m_B / m_A$. This same result is derived in Exercise 8.26 using conservation of linear momentum.

Q8.23 (a) False. As the apple falls it gains speed and its momentum increases because of the net force on it due to gravity. (b) True. No nonconservative forces act on the apple so its mechanical energy is conserved. Gravitational potential energy is converted to kinetic energy. (c) False. (d) False. It gains kinetic energy, because positive work is done on it by the net force on it, the gravity force.

Q8.24 (a) True. If it is assumed that no net external force acts on the clay during the collision, then the momentum of the system is conserved. (b) False. When objects stick together in a collision, the collision must be inelastic and kinetic energy is not conserved. Mechanical energy is not conserved because of the work done during the collision by the nonconservative forces that the pieces of clay exert on each other. This work converts some of the initial kinetic energy into thermal energy and energy of deformation. (c) False. (d) False.

Q8.25 Newton's third law says that the magnitude of the force exerted on each mass is the same. These forces act for the same length of time, until the masses lose contact with the spring. Therefore, the magnitude of the impulse applied to each mass is the same. But the lighter mass moves a greater distance while they are in contact with the spring so more work is done on the lighter mass. (a) Equal magnitude of impulse means that the masses receive equal magnitudes of momentum. (b), (c) and (d). More work is done on the lighter mass so it gains more kinetic energy than the heavier mass. Or,

$K = \dfrac{p^2}{2m}$. Equal momentum means greater kinetic energy for the lighter mass.

Q8.26 The magnitudes of momentum changes for the two vehicles are equal. By Newton's third law, the force the SUV exerts on the compact car has the same magnitude as the force the compact car exerts on the SUV. But such a collision won't be elastic and the kinetic energy of the system is not conserved and the kinetic energy changes for each object won't be equal in magnitude. (a) False. (b) True. (c) False. (d) False.

CHAPTER 9
ROTATION OF RIGID BODIES

Discussion Questions

Q9.1 Yes for (a), (b), (d) and (e). In each case the equation is true for any instant of time. Changes of quantities over time don't enter into the equation, so it doesn't matter how ω and α are changing. No for (c). If α changes with *t* then the equation doesn't even have precise meaning. What value of α would be used, the value at $t = 0$ or the value at the final *t* or something else?

Q9.2 (a) The mass of the molecule has the same distribution about the *x*-axis as it does about the *z*-axis. Therefore, the moment of inertia of the molecule for the *x*-axis as the axis of rotation is the same as for the *z*-axis. The kinetic energy will be *K*. (b) If the atoms are treated as point masses, the mass lies on the *y*-axis and the moment of inertia for the *y*-axis as the rotation axis is zero and the kinetic energy will be zero.

Q9.3 The tangential acceleration is tangential to the circular path of the point. The tangential acceleration is equal to the rate of change of the linear speed of the point. The radial acceleration is radially inward, toward the center of the circular path of the point. The radial acceleration expresses the rate of change of the direction of the velocity of the point.

Q9.4 Yes, a is the rate of change of the speed so it is the same for all points on the chain. $v = r_{\text{rear}}\omega_{\text{rear}} = r_{\text{front}}\omega_{\text{front}}$ so $\omega_{\text{front}} / \omega_{\text{rear}} = r_{\text{rear}} / r_{\text{front}}$. The angular acceleration is the rate of change of the angular speed ω so $\alpha_{\text{front}} / \alpha_{\text{rear}} = r_{\text{rear}} / r_{\text{front}}$. ω and α are larger for the smaller sprocket.

Q9.5 $a_{\text{rad}} = v^2 / r$ and v is the same at the rim of each sprocket, so $a_{\text{rad,rear}} r_{\text{rear}} = a_{\text{rad,front}} r_{\text{front}}$ and $a_{\text{rad,rear}} / a_{\text{rad,front}} = r_{\text{front}} / r_{\text{rear}}$; a_{rad} is larger at the rim of the smaller sprocket.

Q9.6 The tangential acceleration is the rate of change of the angular speed so for constant angular velocity the tangential acceleration is zero. The radial acceleration is $a_{\text{rad}} = r\omega^2$ so if ω is constant, a_{rad} is constant. The direction of a_{rad} is always toward the center of the flywheel, but this direction changes in space as the flywheel rotates.

Q9.7 The spin cycle removes water from the clothes. The clothes turn at the rim of the drum with a large angular speed so they have a large inward radial acceleration $a_{\text{rad}} = r\omega^2$. The force on the water isn't large enough to provide this acceleration to the water and the water doesn't stay in the circular path of the clothes. It leaves tangentially through holes in the drum.

Q9.8 $K = \frac{1}{2} I\omega^2$. Since all the objects have the same ω, the object with the largest I has the largest K and the object with the smallest I has the smallest K. The moment of inertia for each object is:

$I_a = \frac{2}{5} MR^2 = \frac{1}{10} MD^2$

$I_b = \frac{1}{2} MR^2 = \frac{1}{8} MD^2$

$I_c = MR^2 = \frac{1}{4} MD^2$

$I_d = \frac{1}{12} ML^2 = \frac{1}{12} MD^2$

Since all the objects have the same M, the smallest I is I_d and the largest I is I_c. Object *c* has the greatest kinetic energy and object *d* has the least.

Q9.9 It is not possible for a body to have the same moment of inertia for all possible axes. The mass of the body cannot be distributed the same relative to all axes, including those that lie outside the body. Yes, a sphere has the same moment of inertia for all axes passing through its center.

Q9.10 To maximize the moment of inertia the mass should be as far from the rotation axis as possible. This is achieved when all the mass is at the rim, when the flywheel has the shape of a thin-walled hollow cylinder or hoop.

Q9.11 Mount the object on a horizontal axle of radius R that lies along the axis. Let the axle turn in frictionless bearings. Wrap a light cord around the axle and suspend a mass m from the free end of the cord, as in Fig.9.17. Release the system from rest and measure the linear speed v of the mass m after it has descended a vertical distance h. Conservation of energy gives $mgh = \frac{1}{2}I\omega^2 + \frac{1}{2}mv^2$. Use $\omega = v/r$ and solve for I.

Q9.12 No. The farthest each piece of mass can be from the axis is R and the largest possible moment of inertia about the symmetry axis is MR^2.

Q9.13 The thin plate can be constructed from thin rods laid side to side, parallel to side a. Each rod, of mass m_i, has $I_i = \frac{1}{3}m_i a^2$. The total I is the sum of the contribution from each rod and is $I = \sum I_i = \frac{1}{3}(\sum m_i)a^2 = \frac{1}{3}Ma^2$, where M is the sum of the masses of the rods and therefore is the mass of the plate.

Q9.14 $I = \frac{2}{3}MR^2$. $K = \frac{1}{2}I\omega^2 = \frac{1}{3}MR^2\omega^2$. Let K' be the new kinetic energy, $K' = \frac{1}{3}M(R')^2\omega^2$. $K' = 3K$ so $(R')^2 = 3R^2$ and $R' = \sqrt{3}R$.

Q9.15 The cross section of the rod need not be circular for these equations to apply. For the equations to apply, all points on a thin-slice must be to a good approximation the same distance from the axis. For this to be so, the lateral dimensions of the rod must be much less than its length.

Q9.16 The discussion in Q9.15 applies to part (d). For part (c) the thickness of the plate has no effect on how the mass is distributed relative to the axis so the thickness of the plate doesn't matter.

Q9.17 Ball *A* will have more kinetic energy. Conservation of energy applied to the system of the ball and the pulley gives $mgd = \frac{1}{2}I\omega^2 + \frac{1}{2}mv^2$, where *d* is the distance the ball has fallen and *m* is the mass of the ball. $\omega = v/R$. Pulley *B* has a greater moment of inertia for rotation about an axis at its center. Therefore, for a given *d*, more of the total kinetic energy of the system will reside with the pulley in case *B* and therefore the kinetic energy of the ball will be less.

Q9.18 Greater than *V*. Moving the balls closer to the drum decreases the moment of inertia of the pulley about its rotation axis. $v = R\omega$, where R is the radius of the drum and is constant. Conservation of energy gives $mgd = \frac{1}{2}I(v/R)^2 + \frac{1}{2}mv^2$. Smaller *I* means that the pulley has a smaller fraction of the total kinetic energy of the system and for a given *d* the kinetic energy of the box therefore is greater.

Q9.19 In the constant angular acceleration equations (9.7), (9.10), (9.11) and (9.12) you can use any angular measure. The same number of angular quantities appear in each term of the equations so converting from one angular measure to another would just multiply the whole equation by an overall factor, and this doesn't change the equation. $s = r\theta$ requires that θ be in radians; this equation in fact defines the radian. Equations (9.13) through (9.15) and Eq.(9.17) are all derived using $s = r\theta$ so they also require the use of radian measure.

Q9.20 No. A simple counter-example is the solid sphere. The moment of inertia through the center of the sphere is $2MR^2/5$. The center of mass is at the center of the sphere so calculating I by placing all the mass at the center of mass gives the incorrect value of zero.

Q9.21 (a) All points have the same angular speed; it is the same at A and B. (b) $v = r\omega$ so the tangential speed is greater at point A. (c) The angular acceleration α is the time rate of change of the angular velocity, so α is the same at A and B. (d) $a_{\text{tan}} = r\alpha$ so is larger at A. (e) $a_{\text{rad}} = r\omega^2$ so is larger at A.

Q9.22 A simple model for my body is a vertical cylinder with mass *M* and radius *R* and two slender rods for my outstretched arms. I estimate the radius of this cylinder to be about 0.15 m. My height is about 1.7 m so the volume of the cylinder is $V_{\text{cyl}} = \pi R^2 h = 0.12\ \text{m}^3$. For each outstretched arm, the distance from the tip of my fingers to the center of my chest is about $L_{\text{arm}} = 0.90$ m and the average radius for each arm, modeled as a cylinder, is about $R_{\text{arm}} = 0.080\ \text{m}$. So, the volume of each arm, in this simple model, is $V_{\text{arm}} = \pi R_{\text{arm}}^2 L_{\text{arm}} = 0.018\ \text{m}^3$. My total volume then is about $0.17\ \text{m}^3$ and about 11% of my volume is in each arm and therefore 78% is in the rest of my body. My total mass is 82 kg. If the average density of my arms is assumed to be the same as for the rest of my body, then the mass of each of my arms is $M_{\text{arm}} = 9.0\ \text{kg}$ and the mass of the rest of my body is $M = 64\ \text{kg}$. Therefore, my moment of inertia about the specified axis is $I = I_{\text{trunk}} + I_{\text{arms}}$.

$I_{\text{trunk}} = \frac{1}{2}MR^2 = \frac{1}{2}(64\ \text{kg})(0.15\ \text{m})^2 = 0.72\ \text{kg}\cdot\text{m}^2$.

$I_{\text{arms}} = 2\left(\frac{1}{3}M_{\text{arm}}L_{\text{arm}}^2\right) = \frac{2}{3}(9.0\ \text{kg})(0.90\ \text{m})^2 = 4.9\ \text{kg}\cdot\text{m}^2$.

My total moment of inertia is therefore approximated to be $5.6\ \text{kg}\cdot\text{m}^2$. My outstretched arms have a much greater *I* than the rest of my body, even though they have only about 20% of my mass because for them their mass is distributed farther from the axis.

CHAPTER 10
DYNAMICS OF ROTATIONAL MOTION

Discussion Questions

Q10.1 Yes. For example, a force applied tangentially to the rim of a disk initially at rest on a horizontal frictionless surface produces both a net force that accelerates the center of mass of the object and also a torque that starts the disk rotating about the center of mass.

Q10.2 It is better to use small, light wheels. Some of the initial gravitational potential energy of the racer is converted into rotational kinetic energy $\frac{1}{2}I\omega^2$ of the wheels. You want this to be as small as possible, so that most of the potential energy goes into translational kinetic energy of the center of mass of the racer. For the same reason, it is better to use solid wheels, that have a smaller I for the same total mass of the wheel.

Q10.3 Reducing the weight of the wheels reduces the moment of inertia of the wheels and less torque is required to give them a given angular acceleration. Reducing the total mass of the bike also reduces the net horizontal force required for a given linear acceleration but for this motion it doesn't matter where on the bike the weight is removed.

Q10.4 The friction force that opposes the motion of the car while stopping produces a torque about the center of gravity of the car that tends to rotate the car such that the rear is raised and the front is lowered. See Fig. DQ10.4a. When accelerating, the friction force is in the direction the car is moving and produces a torque about the center of gravity that tends to rotate the car in the opposite direction, so the front end is raised. See Fig. DQ10.4b. For a large acceleration the normal force at the front wheels is reduced, so traction is lost there.

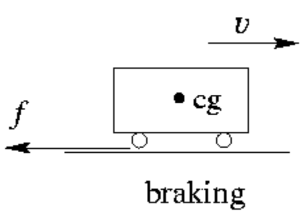

Figure DQ10.4a

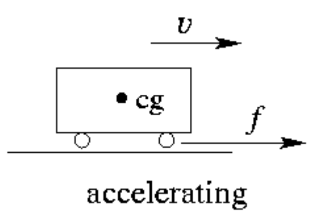

Figure DQ10.4b

Q10.5 Holding her arms out increases her moment of inertia for an axis through her center of mass. By Eq.(10.7), this means a given gravity torque that arises when she leans slightly to one side or the other produces a smaller angular acceleration.

Q10.6 The grinding wheel increases the moment of inertia of the shaft. The torque applied by the motor then produces a smaller angular acceleration.

Q10.7 For work, the distance used is the component of displacement along the direction of the force. For torque, the distance used is the component perpendicular to the force of the distance from the axis to the point of application of the force. Work and torque have the same units but are different quantities.

Q10.8 Roll it down the incline, alongside a solid ball and then alongside a hollow ball. A solid ball will reach the bottom of the incline before a hollow ball.

Q10.9 $\tau = I\alpha$. $I = \int r^2\, dm$. $m = \rho V$ so $dm = \rho\, \mathrm{d}V$ and $I = \rho\int r^2\, dV$. If each dimension is doubled, then I is increased by a factor of $2^5 = 32$. The angular acceleration of the larger object will be $\alpha/32$. For a specific example of a disk with radius *R*, thickness *t* and axis as in Fig. 9.4f, $I=\frac{1}{2}MR^2=\frac{1}{2}\rho\left(\pi R^2t\right)R^2=\frac{1}{2}\rho\pi R^4t$. Doubling *R* and *t* increases *I* by a factor of 2^5.

Q10.10 For the hanging mass, $mg-T=ma$. For the pulley, $TR=I\alpha$. $\alpha=a/R$ so $T=\left(I/R^2\right)a$. $mg=\left(\frac{I}{R^2}+m\right)a$ and $a=\frac{mg}{\left(I/R^2\right)+m}$. $T=\left(\frac{I}{R^2}\right)a=\frac{\left(I/R^2\right)mg}{m+\left(I/R^2\right)}=\frac{mg}{\frac{R^2m}{I}+1}$. The pulley in the shape of hoop has larger *I* and therefore the tension *T* in the string is greater in that case. One way to see this qualitatively is to note that the greater rotational inertia of the loop causes the mass to fall with less downward acceleration when this pulley is used. The smaller *a* is for the hanging mass, the closer the tension is to the weight of the hanging mass. Note that to have the same mass and radius, the hoop must be made of material of greater density than the solid pulley.

Q10.11 The gravity torque acts at the center of gravity of the baton and therefore produces no angular acceleration about this point.

Q10.12 $\frac{1}{2}mv^2+\frac{1}{2}I\omega^2=mgh_0$, where v and ω are the linear and angular speeds of the ball at the bottom of the hill. $I=\frac{2}{5}mR^2$ and $v=R\omega$, so $\frac{1}{2}mR^2\omega^2+\frac{1}{5}mR^2\omega^2=mgh_0$. $h_0=\frac{7R^2\omega^2}{10g}$. (a) The height reached by the ball for a given angular speed at the bottom is proportional to R^2. So, the height reached will be $4h_0$ if *R* is doubled. (b) The mass divides out of the conservation of energy expression so the maximum height will still be h_0. (c) Same as in part (a), $4h_0$. (d) The height reached is proportional to ω^2, so the maximum height will be $4h_0$.

Q10.13 Refer to Fig.10.13. All points have $\vec{\boldsymbol{r}}_{\text{cm}}$ to the right. The resultant velocity of each point is thus $\vec{\boldsymbol{r}}_{\text{cm}}$ to the right plus the velocity for rotation around the center of mass. All points have a velocity component to the right so there is no point where the velocity is purely vertical. The rotation gives a maximum component $-\vec{\boldsymbol{r}}_{\text{cm}}$, that is to the left. The point of contact with the surface has a resultant velocity of zero, but no point has a horizontal component opposite to the velocity of the center of mass. If the wheel is slipping, the speed at the rim due to rotation is greater than v_{cm}. It is still correct that no point has a purely vertical velocity, but now the top of the wheel can have a horizontal velocity opposite to the velocity of the center of mass.

Q10.14 Let the moment of inertia of each object be $I=\beta MR^2$, where β is a different constant for each object. The object with the smallest β reaches the bottom first. For a hoop, $\beta=1$; for a uniform solid cylinder, $\beta=\frac{1}{2}=0.50$; for a spherical shell, $\beta=\frac{2}{3}=0.67$, and for a uniform solid sphere, $\beta=\frac{2}{5}=0.40$. So, the order of arrival, first to last, is: solid sphere, solid cylinder, spherical shell, and hoop. The mass and radii divide out in the calculation of the speed at the bottom of the incline, so it doesn't matter if the mass and radii are the same. All that matters is the shape, the way in which the mass is distributed relative to the axis.

Q10.15 The ball will go higher up the hill if the hill has enough friction to prevent slipping.
energy conservation: As the ball rolls on the horizontal surface at the bottom of the hill it has both translational and rotational kinetic energy. If the hill is perfectly smooth the ball continues to rotate with the same angular speed and only the initial translational kinetic energy is converted into gravitational potential energy; at the maximum height up the hill the ball is still spinning at the same

rate as initially. If there is enough friction to prevent slipping then the ball has stopped rotating at the maximum height and both the initial translational and rotational kinetic energies are converted into gravitational potential energy.
Newton's 2nd law: When there is no friction the net force on the ball as it rolls up the hill is $mg\sin\alpha$ directed down the incline (α is the slope angle of the hill). With friction, there is a friction force f directed up the incline and the net force down the incline is $mg\sin\alpha - f$. With friction the acceleration opposing the translational motion is less and the ball travels a greater distance before coming to rest.

Q10.16 Consider yourself plus the turntable as the system. There are no external torques on this system, so the total angular momentum is constant. As you move farther from the axis the moment of inertia of the system increases and in order to maintain the same angular momentum the rotation speed decreases.

Q10.17 In the oceans the water will be farther from the axis of rotation of the earth than when it is frozen as ice near the poles. The moment of inertia of the earth will increase and from conservation of angular momentum the rotation rate will decrease. The length of a day (the time for one full rotation) will increase.

Q10.18 Since angular momentum is given by $L = I\omega$ and rotational kinetic energy is given by $K_{\text{rot}} = \frac{1}{2}I\omega^2$, $K_{\text{rot}} = \dfrac{L^2}{2I}$. If they have the same L, they will have the same K_{rot} only if they have the same I. And since $L = \sqrt{2IK_{\text{rot}}}$, if they have the same rotational kinetic energy they will have the same angular momentum only if they have the same I. And rotational kinetic energy is a scalar whereas rotational kinetic energy is a vector. Even if they have the same magnitude of angular momentum the angular momentum vectors of the two objects could be different if they are in different directions.

Q10.19 The weights have the same angular velocity, and hence the same angular momentum, just after they are released as just before they were released. The angular momentum of the student doesn't change and her angular speed remains the same. Her angular speed would change if she threw the weights in the tangential direction, instead of just letting go of them.

Q10.20 The particle has angular momentum with constant magnitude $L = mvl$.

Q10.21 The equation $\sum \tau_z = I\alpha_z$ is valid only for rigid bodies, for which I is constant. Eq. (10.29) is always true whereas Eq.(10.7) is true only if I is constant. There is an analogous statement for the dynamics of translational motion: Eq.(8.4) is true in general; $\sum \vec{\boldsymbol{F}} = m\vec{\boldsymbol{a}}$ is equivalent, and correct, only when the mass m of the system is constant during the motion.

Q10.22 Eq.(10.22) is derived using Eq.(10.7), which is correct only when I is constant. When I is not constant, Eq.(10.22) does not apply. The extra kinetic energy comes from the work done by the radial force the professor applies when he pulls in the weights.

Q10.23 Her linear momentum is not conserved, because of the net force on her due to gravity. The force acts at her center of gravity, so provides no net torque for rotation about her center of gravity.

Q10.24 When you stop the raw egg, the raw insides of the egg, which are only loosely coupled to the shell, keep spinning. This energy couples back to the motion of the light shell when the egg is released. When you stop a hard-boiled egg, the whole egg stops.

Q10.25 Without the small rotor, when the large rotor changes angular speed the helicopter body would rotate in the opposite direction to conserve angular momentum. The small rotor causes an external torque from the air that keeps the body of the helicopter from rotating. The two counter-rotating main rotors have zero total angular momentum regardless of their angular speed.

Q10.26 So long as the center of gravity is directly above the pivot there is no gravity torque to cause precession about the pivot.

Q10.27 The processional angular speed Ω is given by $\frac{wr}{I\omega}$. (a) If ω is doubled, Ω is halved. (b) If w is doubled, Ω is doubled. (c) If I is doubled, Ω is halved. (d) If r is doubled, Ω is doubled. (e) wr is increased by a factor of four and $I\omega$ is increased by a factor of four. The factors of four cancel and Ω is unchanged.

Q10.28 According to Eq.(10.33), as the angular speed of rotation ω decreases the precession angular speed Ω increases and the precession period decreases. The gyroscope has slowed down due to friction torque at its axis.

Q10.29 This increases the gravity torque and causes the gyroscope to precess at a faster rate.

Q10.30 The spinning bullet has angular momentum that tends to stay constant as the bullet travels through the air.

CHAPTER 11
EQUILIBRIUM AND ELASTICITY

Discussion Questions

Q11.1 Yes, there is no net external force and no net external torque, if the center of mass of the object has zero acceleration and if the rotating object has zero angular acceleration. Each part of the body is not in equilibrium. Each part is moving in uniform circular motion and has a radial acceleration.

Q11.2 (a) Yes. The net force can be zero while the net torque is not zero. For example, there can be two forces acting on the object that are equal in magnitude and opposite in direction. If these forces act at different points on the object they can produce a net torque even though the net force is zero. A simple example of an object in translational equilibrium but not in rotational equilibrium is the cylinder in Fig. 10.9a. (b) Yes. There can be a net force but no net torque. A simple example is a baseball falling without air resistance. There is a net downward force due to gravity but that force acts at the center of gravity of the baseball and produces no torque.

Q11.3 When the wheel no longer tips the added weights have put the center of gravity at the geometrical center of the wheel.

Q11.4 No. The center of gravity of a hollow sphere is at the center of the sphere.

Q11.5 The gravity force on mass dm is greater at the lower end of the rod so the center of gravity is below the center of mass. The gravity force acting at the center of gravity produces a torque on the object about the object's center of mass. This torque orients the object. When the long axis of the object is directed toward the earth, the line of action of the gravity force is along the long axis and produces no torque and this then is a stable orientation. The same effect keeps the long axis of the moon oriented along the line between the center of the moon and the center of the earth.

Q11.6 If the object is suspended at the center of gravity a small rotation of the object does not produce any torque and the equilibrium is neutral. For a point of suspension above the center of gravity, a small rotation of the object produces a restoring torque and the object is in stable equilibrium. For a point of suspension below the center of gravity, a small rotation of the object produces a torque that tends to take the object farther from equilibrium and the object is in unstable equilibrium.

Q11.7 To balance on your tiptoes your body must move forward enough to place your center of gravity directly above your toes. When you are standing next to the wall and facing it, the wall prevents this from happening.

Q11.8 When the horseshoe hangs in equilibrium, the gravity torque on it is zero and the center of gravity of the horseshoe is directly below the point of support. Draw a chalk line on the wall behind the string. Pivot the horseshoe about another nail hole and again draw a chalk line along the string. The center of gravity is where these two lines intersect. The center of gravity will not be within the solid material of the horseshoe.

Q11.9 The torque due to the weight of the combined object can be calculated by assuming that the gravity force acts at the center of gravity. Therefore, there is no torque about this point and the object doesn't rotate. The bar remains horizontal as it falls.

Q11.10 The torque about the center of gravity due to the gravity force is still zero and the bar remains at 60° above the horizontal as it falls.

Q11.11 The free-body force diagram for the water skier is given in Fig. DQ11.11. $\vec{F}$ is the force of the tow rope and $\vec{f}$ is the resistive force exerted by the water. She leans backward to increase the moment arm and hence the torque produced by her weight about an axis at her feet. This torque opposes the torque due to the force $\vec{F}$ applied to her by the tow rope. $\vec{F}$ must equal the resistive force $\vec{f}$. When her speed increases, f increases and F increases so she must lean back farther to increase the gravity torque.

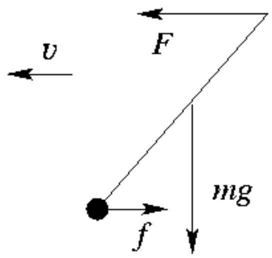

Figure DQ11.11

Q11.12 Pushing near the rim of the wheel gives greater torque about the axle than pushing on the wagon, since the pushing force has a larger moment arm.

Q11.13 He cannot do this. As soon as a vertical line through his center of gravity extends beyond his toes there will be a net torque on him for a horizontal axis through his center of gravity and he will fall over.

Q11.14 With your arm extended there is a large torque about your shoulder due to the weight of the dumbbell and your muscles must exert an equal opposing torque.

Q11.15 I know from experience that over time the distribution of a person's body mass changes, for example moving toward their midsection. This redistribution of mass changes both the location of the person's center of gravity and also the moment of inertia about an axis through the center of mass.

Q11.16 They add more weight in their abdomen region, extending away from their spine. They have to lean backward a bit to keep their center of gravity from extending horizontally past their feet.

Q11.17 The glass tips when its center of gravity is above a point beyond the bottom edge of the glass. If the water in the glass raises the center of gravity this will make the glass more unstable. Whether or not this will be the case depends on how the mass of the glass is distributed. Adding water does increase the moment of inertia, so more torque is required to start it rotating away from equilibrium.

Q11.18 To slide the refrigerator the horizontal force you apply must equal the force of friction from the floor. Whether it starts to slide first or tip first depends on how far above the floor you push. The higher up you push the greater the moment arm for your force and the more torque it produces for a given magnitude of force.

Q11.19 The tension in the wire has a component to the right and the weight of the bar is a vertical force so the force the hinge exerts must have a component to the left. The tension in the wire has an upward component and the weight of the bar is a downward force so you can't use the vertical forces to decide if the hinge force has an upward or downward component. Consider torques on the bar for an axis at the point where the wire is attached to the bar. For this axis, the weight of the bar produces a counterclockwise torque. The torques must sum to zero so the hinge force must produce a clockwise torque and the vertical component of the hinge force is downward.

Q11.20 The Young's modulus of a wire depends only on the material of which the wire is made and does not depend on the length or cross-sectional area of the wire.

Q11.21 $\Delta l = \left(\dfrac{F_\perp}{AY}\right) l_0$. $F_\perp = W$ and $A = \pi D^2/4$, so $\Delta l = \left(\dfrac{4W}{\pi D^2 Y}\right) l_0$. For the new value of W, $\Delta l' = \left(\dfrac{4W'}{\pi (D')^2 Y}\right) l_0'$. But $\Delta l' = \Delta l$ and $l_0' = l_0$ (same original length, same amount of stretch). This gives $\left(\dfrac{4W}{\pi D^2 Y}\right) l_0 = \left(\dfrac{4W'}{\pi (D')^2 Y}\right) l_0$. $W' = \left(\dfrac{D'}{D}\right)^2 W$. $W' = 3W$ gives $3 = \left(\dfrac{D'}{D}\right)^2$ and $D' = \sqrt{3} D$.

Q11.22 They have the same tensile strength but the cable is much more flexible. This can be an advantage or disadvantage depending on the application.

Q11.23 The weight of the elephant is much greater so the same stress requires bones of greater cross section.

Q11.24 The excess energy in each deformation cycle is deposited in the tendon and can build up to damaging levels after a large number of rapid cycles.

Q11.25 The excess energy during each vibration cycle is deposited as thermal energy in the rubber mounting blocks.

CHAPTER 12
FLUID MECHANICS

Discussion Questions

Q12.1 For a submerged cube the buoyant force is the difference between the downward force exerted by the water at the top face of the cube and the upward force exerted by the water at the bottom face of the cube. The pressure at these two locations is different so the forces are different. If there is truly no water under the cube, between the bottom face of the cube and the bottom of the tank, then there is no upward force due to the water pressure there and the block doesn't rise to the surface when released. But in practice this would be very unstable and difficult to achieve. At the bottom face of the cube there are large horizontal forces due to the water pressure there that tend to push water under the block. If only a thin film of water gets under the block the buoyant force returns to its normal value and the block floats to the surface.

Q12.2 The pressure at a given point depends only on the height of the fluid surface above that point. Therefore, the pressure at a given depth below the surface for water in the hose is the same as the pressure at the same depth below the surface in the funnel. The upward force that supports the weight of the water in the funnel comes partly from the upward force due to the pressure in the water at the bottom of the funnel and partly from the sloped sides of the funnel.

Q12.3 The force on the floor is not due just to the weight of the air in the room, but is due to the entire column of the earth's atmosphere above the floor.

Q12.4 The distance the small piston moves is a factor of A_2 / A_1 larger than the distance the large piston moves. So the work done by F_1 equals the work done by F_2 and energy is conserved.

Q12.5 The total force of the pavement on the tires must equal the weight of the car. $F = pA$ so smaller pressure p requires a larger area A.

Q12.6 Hot air has a smaller density than the surrounding air so the buoyancy force is larger than the weight when the balloon is filled with hot air. The density of the air in the balloon depends on the temperature of this air; the ascent or descent is controlled by varying the temperature of the air in the balloon.

Q12.7 This is the weight of the water displaced by the floating ship. This equals the buoyant force and must equal the weight of the ship.

Q12.8 No. As the elevator accelerates upward, more upward force on the sphere is needed to make the sphere accelerate upward with the elevator. The sphere continues to sit on the bottom of the bucket no matter how great the upward acceleration of the elevator is. The buoyant force is $\rho_{\text{fl}} V_{\text{sp}}(g+a)$, where ρ_{fl} is the density of the water and V_{sp} is the volume of the sphere. Newton's 2nd law applied to the sphere gives $n + B - mg = ma$, where n is the normal force the bottom of the bucket exerts on the sphere. This gives

$$n = m(g+a) - B = \rho_{\text{sp}} V_{\text{sp}}(g+a) - \rho_{\text{fl}} V_{\text{sp}}(g+a) = V_{\text{sp}}(g+a)(\rho_{\text{sp}} - \rho_{\text{fl}}),$$

where ρ_{sp} is the density of the sphere. As a increases, the upward normal force n that the bottom of the bucket exerts on the sphere also increases.

Q12.9 The density of the atmosphere decreases with altitude so the buoyant force on the dirigible decreases with altitude. The dirigible rises until the density of the surrounding air equals the average density of the dirigible (frame plus cargo plus helium).

Q12.10 Assume that in each case the liquid is the same. The buoyant force is equal to $\rho_{\text{liquid}}V_{\text{submerged}}g$. For the piece of iron the volume submerged is $(25\text{ cm})^3$. For the floating piece of wood the volume submerged is less than $(25\text{ cm})^3$. Therefore, the buoyant force on the iron is greater. The buoyant force on the piece of wood equals the weight of the piece of wood and the buoyant force on the piece of iron is less than the weight of the piece of iron. But the density of iron is much larger than the density of wood so for equal volumes the weight of the piece of iron is much larger than that of the piece of wood.

Q12.11 The weight in air is $w_{\text{air}} = mg = \rho_{\text{obj}}V_{\text{obj}}g$, where ρ_{obj} and V_{obj} are the density and volume of the object. The "weight" in water is $w_{\text{w}} = w_{\text{air}} - B = \rho_{\text{obj}}V_{\text{obj}}g - \rho_{\text{w}}V_{\text{obj}}g = (\rho_{\text{obj}} - \rho_{\text{w}})V_{\text{obj}}g$, where ρ_{w} is the density of water. $w_{\text{air}} / w_{\text{w}} = \rho_{\text{obj}} / (\rho_{\text{obj}} - \rho_{\text{w}})$ so if w_{air} and w_{w} are measured, ρ_{obj} can be calculated. The density of the object measured in this way can be compared to the density of pure gold. To make your fake brick pass this test the average density of the brick would have to equal that of gold. Table 12.1 shows that few materials have a density as large as that of gold. You could gold-plate a platinum-brass alloy brick, for example, but to have the same density of gold it would have to be mostly platinum, and platinum is very expensive.

Q12.12 Pressure varies with depth so the force on each square centimeter of levee is greatest at the bottom.

Q12.13 In each case the buoyant force B must equal the weight of the floating ship. $B = \rho_{\text{fl}}V_{\text{displ}}g$, where ρ_{fl} is the density of the fluid and V_{displ} is the volume of the ship that is beneath the surface of the water. The density of fresh water is a bit less than the density of sea water, so V_{displ} must be greater in fresh water to produce the same buoyant force.

Q12.14 With the wood completely submerged the buoyant force is equal to $\rho_{\text{water}}V_{\text{wood}}g$, where ρ_{water} is the density of the water and V_{wood} is the volume of the piece of wood. The buoyant force increases very slightly with depth because the density of the water increases slightly with depth, due to the increase of pressure with depth. But for the depth of a swimming pool the increase in density from near the surface to the bottom of the pool is very small and to a good approximation the buoyant force on the piece of wood remains constant as the wood is pushed deeper under the water.

Q12.15 A mass of feathers for which the weight is one pound has a much larger volume than a mass of lead for which the weight is one pound. The larger volume for the feathers would have a much larger buoyant force from the air and the net downward force on the feathers would be less than that on the lead. It would take more than a pound of feathers to balance a pound of lead.

Q12.16 The pressure difference would be (0.01)(1.0×10^5 Pa) = 1.0×10^3 Pa. For a door with area 2 m^2 the net force keeping the door closed would be 2×10^3 N. This is about 450 pounds. It would take a very strong person to pull the door open. But all that would be required would be to open it slightly, so air can move from the high pressure to the low pressure side. Once the pressure is equalized the door will easily open the rest of the way.

Q12.17 The pressure at depth h in an incompressible fluid is given by $p = p_0 + \rho gh$, where

p_0 is the pressure at the surface. When the depth h is doubled, the ρgh term doubles. But p doesn't double, because of the p_0 term. The gauge pressure doubles but the absolute pressure is less than $2p$.

Q12.18 When the block floats, the weight of water displaced equals the total weight of the block. Since it floats, the average density of the block plus iron must be less than the density of the water. The block still floats when the block is turned over. In either case the same amount of water is displaced, an amount whose weight equals that of the block, so the water level in the bucket doesn't change.

Q12.19 As the jar is pushed deeper the water pressure increases and the air inside the jar is compressed to a smaller volume. More water enters the jar so less water is displaced by the jar plus air bubble and the buoyant force on the jar decreases.

Q12.20 When the bowling ball is sitting in the floating canoe it must cause an amount of water to be displaced that is equal to the weight of the bowling ball. When the bowling ball is sitting at the bottom of the pool the buoyant force on it is less than its weight, since it sinks, so it is displacing less than its weight of water. The bowling ball causes less water to be displaced when it has been dropped over the side, so the water level in the pool falls.

Q12.21 The buoyant force is increased by an amount equal to the weight of the bird so the canoe sinks lower to displace more water and the level of water in the pool rises.

Q12.22 Consider a bucket full of water. When the piece of wood is placed in the water the buoyant force on the floating piece of wood equals its weight. This buoyant force also equals the weight of the water displaced by the piece of wood. Therefore, the weight added by placing the piece of wood in the water equals the weight of the water that flows over the side of the bucket and the weight of the contents of the bucket doesn't change. The two buckets weigh the same.

Q12.23 When the ice cube is floating it displaces an amount of water whose weight equals its weight. The amount of water produced from the melted ice has a weight equal to that of the ice cube; the mass doesn't change during the melting. These two amounts of water are the same, so the water level in the glass doesn't change.

Q12.24 The balloons move forward toward the front of the car. The air in the car has the same acceleration as the car. The force that produces this acceleration for a volume of air is exerted by the surrounding air. When this volume is replaced by a helium-filled balloon, the force on the balloon exerted by the surrounding air is the same as when just air was in the volume. But the helium-filled balloon has less mass that the same volume of air (the balloon rises if released), so the same force produces a greater acceleration when applied to the balloon and the balloon has a greater forward acceleration than does the air inside the car.

Q12.25 The velocity of the fluid at a given point in space is constant in time but the velocity at different points can be different. A fluid particle accelerates when it moves to a point where the velocity is different.

Q12.26 The pressure is less in the moving stream of air than it is in the surrounding stationary air.

Q12.27 The pressure is less in the rapidly rotating air, where the air is moving at high speed. The air pressure difference gives rise to large forces, since normal air pressure is large.

Q12.28 Atmospheric pressure is less at higher elevations so for the same wing speed and shape the pressure difference between points above and below the wing is less at higher elevations.

Q12.29 See Problem 12.84. As the water falls it gains speed due to gravity. The continuity equation says that the cross-sectional area decreases when the fluid speed increases.

Q12.30 "Identical-sized" means the two cubes have equal volumes. But lead has a greater density than aluminum so the mass of the lead cube will be greater than the mass of the aluminum cube. (a) The buoyant force on each cube is given by $B = \rho_{\text{water}} V_{\text{water}} g$. Since the cubes have equal volumes the buoyant force is the same on each. (b) The tension in the wire is given by $T = mg - B$. B is the same for both but mg is greater for the lead cube and therefore the tension in the wire is greater for the lead cube. (c) The force on the lower face of each cube is $F = p_1 A$, where A is the area of the lower face and $p_1 = p_0 + \rho g h$ is the pressure at the lower face. Figure Q12.30 shows that the lead cube is suspended at a greater depth in the water. So, the pressure at its lower face is greater than for the aluminum block and the force on its lower face is greater than for the aluminum block. But, the pressure at the upper face is also greater and the difference between the upward force on the bottom and the downward force on the top face is the same for the two blocks. (d) The difference in depth between the top and bottom faces is the same for both blocks so the difference in pressure between the upper and lower faces is also the same for both blocks.

CHAPTER 13
GRAVITATION

Discussion Questions

Q13.1 The force the earth exerts on the apple equals in magnitude the force the apple exerts on the earth. By Newton's 2nd law equal forces produce a much smaller acceleration for the much more massive earth.

Q13.2 $g = Gm/R^2$. $m = \rho V = (4/3)\pi R^3\rho$ so $g = 4\pi\rho GR/3$. g at the surface of the planet would be directly proportional to the radius of the planet.

Q13.3 The pound is a unit of force and describes the gravity force on the object. The gravity force on an object is less on Mars so it takes more butter to make a pound on Mars. The kilogram is a measure of mass, which is an intrinsic measure of the amount of material. A kilogram of butter is the same amount of butter on Mars as on the earth.

Q13.4 Because the strength of the gravity force is directly proportional to the mass of an object. More massive objects have greater gravity force on them but require a greater force for the same acceleration. In Example 13.2 the gravitational force is between the two masses. When two masses are dropped near the surface of the earth the gravitational force is between the earth and each mass.

Q13.5 At noon I am on the side of the earth facing the sun and at midnight I am on the side of the earth opposite the sun. So at noon I am closer to the sun by a distance equal to the diameter of the earth and at that point I exert a greater gravity force on the sun.

Q13.6 If there was no net force on the moon it would travel in a straight line at constant speed. A net inward force is required to keep the moon moving in uniform circular motion, and the gravity force exerted by the earth is just what is required to keep the moon moving in a circle of constant radius.

Q13.7 The orbital period for a circular orbit is given by Eq.(13.12): $T = \dfrac{2\pi r^{3/2}}{\sqrt{Gm_{\text{s}}}}$, where we have replaces the mass of the earth, m_{E}, by the mass of the star, m_{s}. $T\sqrt{m_{\text{s}}} = \dfrac{2\pi r^{3/2}}{\sqrt{G}}$, which is constant. Let T_1 be the period for a star of mass m_{s1} and let T_2 be the period for a star of mass m_{s2}. Then $T_1\sqrt{m_{\text{s1}}} = T_2\sqrt{m_{\text{s2}}}$. $T_2 = T_1\sqrt{\dfrac{m_{\text{s1}}}{m_{\text{s2}}}}$. $T_1 = T$ and $m_{\text{s2}} = 3m_{\text{s1}}$. $T_2 = \dfrac{T}{\sqrt{3}}$. The answer is (d).

Q13.8 The orbital period for a circular orbit is given by Eq.(13.12): $T = \dfrac{2\pi r^{3/2}}{\sqrt{Gm_{\text{s}}}}$, where we have replaces the mass of the earth, m_{E}, by the mass of the star, m_{s}. T doesn't depend on the mass of the planet, so the answer is (c) T. Applying Newton's second law to the motion of the planet gives $F_{\text{g}} = ma_{\text{rad}}$. Since the gravitational force F_{g} between the star and the planet is proportional to the mass m of the planet, the mass of the planet divides out of the equation.

Q13.9 The earth and moon orbit together around the sun in an orbit of nearly the same radius and orbital speed.

Q13.10 At a given distance from each, the attractive force of the earth is greater than the attractive force exerted by the moon. So, more fuel is required to go from the earth to the moon than from the moon to the earth.

Q13.11 For a circular orbit the work done is zero. We can see this in either of two ways: the force is radial and the displacement is tangential so no work is done, or, the speed is constant so the kinetic energy is constant and the work-energy theorem says the net work done on the planet is zero, For an elliptical orbit, after one complete orbit the speed has returned to its initial value, the change in kinetic energy is zero and no net work is done. For the elliptical orbit there is a component of force tangent to the path for part of the orbit and the gravity force does do work on the planet. The force does positive work during the part of the orbit where the planet is speeding up and does negative work during the part of the orbit where the planet is slowing down. But the net work for a complete orbit is zero.

Q13.12 In the analysis of Example 13.5 the escape speed is independent of the direction the projectile is launched. But, if air resistance is included the mechanical energy dissipated by work done by the air resistance depends on the path of the projectile through the earth's atmosphere, and this path depends on the direction in which the projectile is launched.

Q13.13 To just barely escape from the earth the initial total mechanical energy of the satellite must be zero, so it can reach a point far from the earth, where the gravitational potential energy is zero, with zero kinetic energy. If the total mechanical energy is less than zero, the satellite rises to a maximum height and then falls back to the surface of the earth. It returns to the earth with the same speed with which it was projected upward. If the initial mechanical energy is greater than zero then it escapes from the earth. When it is very far from the earth it's kinetic energy equals the total mechanical energy it had initially.

Q13.14 The statement is correct. For objects moving near the surface of the earth the elliptical path is approximated well by a parabola.

Q13.15 According to Kepler's 2nd law, a line from the sun to the earth sweeps out equal areas in equal times. As Fig.13.19c shows, the earth moves faster when it is closer to the sun.

Q13.16 Such an orbit is not possible. The gravitational force is directed toward the center of the earth and the plane of all satellites must pass through the center of the earth. The center of the earth is one of the foci of the elliptical orbit of the satellite.

Q13.17 The acceleration is greatest when the force is greatest. This is when the satellite is closest to the object, at the perihelion. The acceleration is least when the force is least, at aphelion.

Q13.18 $F = ma$ would give $A / r^3 = mv^2 / r$, where A is a constant. $v = \sqrt{A / mr^2}$ and $T = 2\pi r / v = 2\pi r^2 (\sqrt{m / A})$. The period would be proportional to the square of the orbit radius. The requirement of elliptical orbits is only for a $1 / r^2$ force so Kepler's first law would no longer hold. Kepler's second law is just a statement of conservation of angular momentum, and this holds for any central force so would be unchanged.

Q13.19 The inertia of the comet causes it to continue to move. Part of the kinetic energy it has at perihelion is converted to gravitational potential energy as the comet moves to apehelion.

Q13.20 Only at an infinite distance from the earth is its gravitational force zero. The gravity force is required to provide the radial acceleration of an orbit. If there were no gravity force on a spacecraft, the spacecraft would travel in a straight line at constant speed. An astronaut feels weightless because the spacecraft and the astronaut have the same acceleration.

Q13.21 The only force on the spacecraft and on the astronaut is gravity and they move with the same acceleration.

CHAPTER 14
PERIODIC MOTION

Discussion Questions

Q14.1 The object travels a total distance of $4A$ in one period. If the amplitude is doubled then this distance doubles. The period does not depend on the amplitude so is unchanged. The maximum speed is given by Eq.(14.23) and doubles when the amplitude doubles. The distance traveled in one cycle doubles but the speed increases just enough to keep the time for one cycle the same.

Q14.2 Swinging of a playground swing; this motion is simple harmonic only for small amplitudes and the motion also loses mechanical energy due to dissipative forces. Pistons in a car engine; force doesn't precisely obey Hooke's law.

Q14.3 Yes. Period or frequency is independent of the amplitude. This is important; pitch generated needs to be independent of how hard the tuning fork is struck and needs not to change as vibrations die away.

Q14.4 (a) $f = \frac{1}{2\pi}\sqrt{\frac{k}{m}}$. The frequency increases because the mass of the oscillating object decreases. (b) $T = \frac{1}{f} = 2\pi\sqrt{\frac{m}{k}}$. The period decreases. (c) The amplitude is given by $\frac{1}{2}kA^2 = E$, where E is the total energy of the system. When the box is at its maximum distance from the equilibrium point, $v = 0$ and all the energy of the system is stored as elastic potential energy in the stretched or compressed spring. Therefore, removing the pebble doesn't alter the total energy of the system and the amplitude doesn't change. (d) Since the total energy of the system doesn't change, the maximum kinetic energy of the box doesn't change. (e) $K_{\text{max}} = \frac{1}{2}mv_{\text{max}}^2$, where K_{max} is the maximum kinetic energy of the box and v_{max} is its maximum speed. K_{max} doesn't change but m is decreased, so v_{max} increases.

Q14.5 The half spring stretches half as much as the full spring for the same applied force, since it has half the number of coils. $k = F/x$ so the force constant of each half is twice that of the full spring. $f = (1/2\pi)\sqrt{k/m}$ so the frequency would be larger by $\sqrt{2}$.

Q14.6 There is no horizontal force on the coin other than the static friction force exerted on it by the glider surface. Since the coin isn't slipping relative to the glider, the static friction force on the coin must give the coin the same horizontal acceleration as the acceleration of the glider. The acceleration of the glider is greatest at the end points of its motion, when it is its maximum distance from its equilibrium position and this is where the static friction force on the coin is the greatest. The acceleration of the glider is zero as it moves through its equilibrium position, and at this point in the motion the static friction force on the coin is zero.

Q14.7 Yes, the center of mass of the system, at the center of the spring, remains at rest just as if that point were attached to a stationary object. The motion is that of a glider attached to a half-spring. The half-spring has twice the force constant of the full spring, so the period is smaller by a factor of $1/\sqrt{2}$ when two gliders are used compared to where there is only one glider and the other end of the spring is kept stationary.

Q14.8 Use the chain and ring to construct a simple pendulum. Measure the period of the pendulum and use $T = 2\pi\sqrt{L/g}$ to calculate g. You will need to estimate the length of the pendulum you have made. Using the data in Appendix F, $g_p = Gm_p / R_P^2$ gives $g_{Mars} = 3.7\ \text{m/s}^2$. The difference between g on Earth and Mars is large and the measurement of g does not need to be very precise.

Q14.9 The period is the same in all three cases. Let d_0 be the amount the spring is stretched when the acceleration of the object equals that of the elevator. Upward acceleration of the elevator requires that d_0 be larger than when the elevator is at rest or moving with constant velocity and downward acceleration of the elevator decreases d_0. But the net force on the object when it is displaced a distance *x* from the d_0 point is still given by $-kx$ and the period is unaffected by the acceleration of the elevator. The acceleration of the elevator is equivalent to changing the value of *g* and it is shown in Section 14.4 that the period doesn't depend on *g* for vertical SHM.

Q14.10 Both the pendulum and the space station would be in free-fall, with the net force on each being gravity. The pendulum would no longer swing back and forth when displaced and released. The period of the object on the spring depends on the force constant of the spring and the mass of the object and would be unchanged.

Q14.11 (a) For a pendulum $T = 2\pi\sqrt{\dfrac{L}{g}}$. An upward acceleration *a* is equivalent to increasing *g* to $9.8\ \text{m/s}^2 + a$. The restoring force is increased and the period decreases. (b) Motion with constant velocity cannot be distinguished from the elevator being at rest. The period is unchanged. (c) A downward acceleration *a* decreasing *g* to $9.8\ \text{m/s}^2 - a$. The restoring force is decreased as the period decreases. (d) The elevator is in free-fall and the pendulum ceases to swing back and forth. There is no restoring force and the period becomes infinite.

Q14.12 (a) $f = (1/2\pi)\sqrt{g/L}$. To double the frequency decrease the length by a factor of 4. (b) $T = 2\pi\sqrt{L/g}$. To double the period increase the length by a factor of 4. (c) $\omega = \sqrt{g/L}$ so decrease the length by a factor of 4, just as in part (a).

Q14.13 g decreases with altitude so the period of the pendulum increases and the clock loses time.

Q14.14 The period of a simple pendulum is independent of the amplitude; so long as the amplitude remains small the period remains the same. When the amplitude is increased the distance traveled in one period is greater. But the restoring force also increases with the angular displacement from equilibrium so the mass moves faster. The two effects compensate and the period is independent of amplitude. The same reasoning and conclusion applies to a physical pendulum. But for larger amplitudes the restoring force is no longer proportional to the displacement and the motion ceases to be simple harmonic. As Figure 14.22 shows, the magnitude of the restoring force is less than proportional to the displacement. A smaller restoring force means a longer period; the period increases when the amplitude decreases. The same reasoning and conclusion applies to a physical pendulum.

Q14.15 The period of oscillation of the shorter leg, treated as a physical pendulum, is less. It is easiest for the dog to walk when its legs swing at their natural frequency, as discussed in Example 14.10.

Q14.16 The tension is in the radial direction. The pendulum mass has a radial acceleration $a_{rad} = v^2 / L$, directed inward. At the end points of the motion, where $v = 0$ and the string makes an angle Θ with respect to the vertical, $a_{rad} = 0$ and $T = mg\cos\Theta$. As the string moves through the vertical position the speed of the mass is a maximum and $T = mg + mv_{\max}^2 / L$. The tension is greater when the string is vertical and is least at the end points.

Q14.17 Yes, such a standard could be used. An advantage is that such a standard is easily reproduced and easy to use. Disadvantages are that it is difficult to measure the period to high accuracy and that the period varies with location, due to variations in g.

Q14.18 The angular frequency ω is equal to $2\pi f$, where $f = \dfrac{1}{T}$ is the frequency of oscillation of the pendulum. $\omega = \sqrt{\dfrac{k}{m}}$ so for a given mass and spring, ω is a constant and doesn't vary during the motion. The angular speed $\omega = d\theta / dt$ is the rate at which the angular displacement of the pendulum is changing. It is equal to v / L, where v is the speed of the pendulum bob and L is the length of the pendulum. The linear speed v is continually changing during the motion so this ω is also changing. ω is zero when the pendulum is at its maximum angular displacement and ω is a maximum when the pendulum is swinging through its equilibrium position, when it is vertical.

Q14.19 The structures should not have natural frequencies in the range of typical earthquake frequencies, to avoid resonance excitation of the frequencies of motion of the structures. Damping should be large so that large amplitude oscillations don't build up.

CHAPTER 15
MECHANICAL WAVES

Discussion Questions

Q15.1 (a) Yes. The frequency depends on whatever is producing the waves. For example, in Fig.15.3 the frequency of oscillation of the block equals the frequency of the waves that it produces on the string. (b) Yes. The wave speed depends solely on the properties of the string, its tension and mass per unit length. So, the answer to (c) is that the two waves on the same string must have the same wave speed. But $v = f\lambda$, so if f is different and v is the same, λ must be different. (c) No. (d) Yes. The amplitude depends on whatever is producing the waves. (e) No. $v = f\lambda$. v must be the same. If f is also the same, then λ can't be different.

Q15.2 If the wave has length L and tension F, the speed of a wave pulse on the wire is $v = \sqrt{\dfrac{F}{\mu}}$. The time it takes a pulse to travel the length of the wire is $t = \dfrac{L}{v} = L\sqrt{\dfrac{\mu}{F}}$. Ignoring a slight stretching of the wire when the tension is increased, L and μ are constant and $t\sqrt{F} = L\sqrt{\mu}$ is constant. Therefore, $t_1\sqrt{F_1} = t_2\sqrt{F_2}$ where $t_1 = 2.00\text{ s}$, $t_2 = 6.00\text{ s}$ and $F_1 = F$. $F_2 = F_1\left(\dfrac{t_1}{t_2}\right)^2 = F\left(\dfrac{2.00}{6.00}\right)^2 = F/9$. The tension must be decreased in order for the wave speed to decrease and for the pulse to take longer to travel the length of the wire.

Q15.3 There is kinetic energy of the moving string and the elastic potential energy of the string when it is displaced from equilibrium. The kinetic energy could be transferred to an object attached to the end of the string.

Q15.4 The energy in the wave decreases. The wave energy is transferred to the thermal energy in the string due to dissipative forces within the string.

Q15.5 The wave speed is independent of the amplitude of the wave. It depends only on the properties of the medium. Eq.(15.14) is an example of this.

Q15.6 The waves slow down as they approach the shore. This causes the water to pile up and produce crests.

Q15.7 The answer is yes to both questions. All that is required is to have a restoring force when a section of the string is displaced longitudinally or when a section of the rod is given a transverse displacement. To produce a longitudinal wave in a stretched string pull longitudinally at a point of the string and release it. The more elastic the string the easier this is to do. To produce transverse waves in a rod, clamp the rod at one end and tap in the transverse direction at some point on the rod. Transverse waves also can be easily set up in a rod clamped at some point by stroking the rod between your fingers.

Q15.8 The wave speed is $v = \sqrt{F/\mu}$. Each part of the string undergoes SHM with maximum speed given by $v_{\max} = \omega A = 2\pi fA$. These two speeds are totally different. The wave speed is constant along the length of the string. At any instant the transverse speed of each point on the string varies along the length of the string and the transverse speed of any point on the string varies in time.

Q15.9 Eq.(15.14) says that waves travel faster on the thin strings, since they have smaller μ.

$f_1 = (1/2L)\sqrt{F/\mu}$, so the fundamental frequency f_1 is higher for the thin strings.

Q15.10 As Eq.(15.21) shows, the power at a point on the string at a given time is given by the product of the transverse force component F_y and the transverse velocity v_y of this point on the string. The product of F_y and v_y always has the same sign, even though v_y is negative as often as it is positive. Therefore, the power $P(x,t)$ at a given location and time is proportional to $\sin^2(kx - \omega t)$ (Eq.(15.23)). This quantity is always positive and its average over one or more cycles is equal to $\frac{1}{2}$, not zero.

Q15.11 $v = \sqrt{F/\mu}$; the wave speed changes when μ changes. The frequency f is the number of cycles per second and won't change. $v = f\lambda$ so when v changes the wavelength λ must also change.

Q15.12 The tension is zero at the bottom of the rope and at the top of the rope the tension is equal to the weight of the rope. $v = \sqrt{F/\mu}$ so the wave speed increases as the pulse travels up the rope (Example 15.3).

Q15.13 The wave disturbance travels along the length of the string. When one section of the string is displaced it exerts a force on the adjacent section and this allows for one section to do work on the adjacent section and to thereby transfer energy to it.

Q15.14 The node never has any displacement. No displacement means no work is done on it by the adjacent sections of the string.

Q15.15 No, a standing wave is not produced if the two waves don't have the same amplitude. Let one wave have amplitude A and the other have amplitude $A + \Delta$. The wave with amplitude $A + \Delta$ can be written as the sum of two waves, one with amplitude A and the other with amplitude Δ. The part with amplitude A combines with the other wave to produce a standing wave but the part with amplitude Δ remains a traveling wave. No, if the two waves have different frequencies they don't combine to form a standing wave. Points at which there is destructive interference at a given time no longer have destructive interference at a slightly later time. Superposition of such waves form beats (Section 16.7) rather than standing waves.

Q15.16 The pitch increases as the rubber band is stretched. As the rubber band is stretched, F increases and μ decreases, so Eq.(15.35) says f increases.

Q15.17 According to Eq.(15.35), to double the frequency the tension in the string must be increased by a factor of four. Therefore, to raise the pitch of the string one octave the tension in the string must be increased by a factor of four. To raise the pitch two octaves the tension must be increased a factor of sixteen. If the tension exceeds the breaking strength of the string, the string will break.

Q15.18 The finger on the middle of the string produces a node there, so the string vibrates in its first overtone. The frequency of the first overtone is twice the fundamental frequency.

Q15.19 The wall prevents longitudinal motion but offers no impediment to transverse motion.

Q15.20 According to Eq.(15.35), all else being equal a longer string has a lower fundamental frequency.

Q15.21 They mark places where the string can be held down to produce fundamental standing waves of different frequencies. The shorter the vibrating portion of a string, the higher the frequency of its fundamental.

CHAPTER 16
SOUND AND HEARING

Discussion Questions

Q16.1 The frequency is the number of cycles per second and doesn't change. The number of cycles arriving per unit time at one side of the interface between the two materials must equal the number leaving the interface on the other side in the same time. The wave speed increases so by $v = f\lambda$ the wavelength must increase.

Q16.2 Compression waves in the metal rails travel faster than sound waves in the air.

Q16.3 The wave speed increases with temperature, so by Eq.(16.18) and (16.22) the pitch increases with temperature.

Q16.4 Different notes correspond to different standing wave patterns in the air columns inside the instrument, to overtones with differing number of nodes. The lowest possible note corresponds to the frequency of the fundamental, but there is no physics limit on the highest note. But higher overtones may be difficult to produce. All the notes must have a frequency that is an integer multiple of the fundamental frequency.

Q16.5 This brings the instrument and the air inside to the same steady-state temperature it will have during the performance. The speed of sound depends on the air temperature, so the pitch of the note is affected by temperature.

Q16.6 The speed of sound in helium is much higher than in air so the standing waves in your vocal track have higher frequency when the vocal track is filled with helium rather than air.

Q16.7 The tires vibrate at the frequency at which the ridges are encountered. This frequency is proportional to the speed of the car.

Q16.8 (a) No. The sound intensity level is given by $\beta = (10\text{ dB})\log\left(\frac{I}{I_0}\right)$. $\beta = 0$ means $I = I_0$, since $\log(1) = 0$. When $\beta = 0$ there is sound, with intensity equal to the reference intensity I_0. (b) Yes. The sound intensity level β is negative when the intensity I is less than the reference intensity I_0. (c) Yes, a sound intensity of $I = 0$ means there is no sound. (d) No, the sound intensity cannot be negative.

Q16.9 The eardrum is set into vibration by pressure variations so the pressure amplitude has the most direct influence. But, these two amplitudes at a given wavelength or frequency are directly proportional to each other (Eq.16.5).

Q16.10 According to Eq.(16.14), the intensity is proportional to the square of the pressure amplitude. If $p_{\max}$ is halved, I decreases by a factor of 4. If the pressure amplitude is increased by a factor of 4, the intensity will increase by a factor of 16.

Q16.11 No. The sound intensity level is given by $\beta = (10\text{ dB})\log\left(\frac{I}{I_0}\right)$. If β obeyed the inverse-square law, doubling *r* would change the sound intensity level from β to $\beta/4$. That is, if at a distance *r* the sound intensity level is 60 dB, at distance $2r$ the sound intensity level would be 15 dB. But Example 16.9 shows that doubling the distance from the source decreases β by 6.0 dB. That is, if at distance r the sound intensity level is 60 dB, then at distance $2r$ the sound intensity level is 54 dB.

Q16.12 The inverse square relationship is Eq.(15.26). If $r_2 > r_1$, the absorption of energy means that I_2 is less than $I_1(r_1/r_2)^2$; the intensity falls off faster than $1/r^2$.

Q16.13 The added mass slows the vibration of the tine and therefore decreases *f*. The sound wave in air has the same frequency as the tine and for the sound wave in air $v = f\lambda$. So, the frequency of the sound wave decreases and its wavelength increases.

Q16.14 The sound wave reflects from the walls and continues to propagate inside the building. The sound energy is converted to thermal energy due to dissipative forces in the air and during the reflections.

Q16.15 The interference is constructive if the path difference is an integer number of wavelengths. It is destructive if the path difference is a half-integer number of wavelengths. For this source, $\lambda = \dfrac{v}{f} = \dfrac{344 \text{ m/s}}{860 \text{ Hz}} = 0.40 \text{ m}$. The path difference is $13.4 \text{ m} - 12.0 \text{ m} = 1.4 \text{ m}$. $\dfrac{1.4 \text{ m}}{0.40 \text{ m}} = 3.5$. The path difference equals 3.5 wavelengths and the interference is destructive.

Q16.16 The observed frequency of the rotating fork is shifted by the Doppler effect. Its pitch is increased when it is moving toward the listener and is decreased when it is moving away from the listener. The listener therefore hears two different frequencies from the two forks and beats occur.

Q16.17 The person is moving toward one source and its pitch is raised and is moving away from the other source and its pitch is lowered. When the two parts of the organ sound the same note the moving listener hears two different pitches.

Q16.18 In Eq.(16.29) the velocities of the listener and source are relative to the medium in which the wave is traveling. In this case this is the air. The direction from the listener to the source is positive. If the wind speed is v_{w}, then $v_{\text{L}} = +v_{\text{w}}$ and $v_{\text{S}} = +v_{\text{w}}$. The factor multiplying f_{S} in Eq.(16.29) is unity and there is no shift in frequency; $f_{\text{L}} = f_{\text{S}}$.

Q16.19 Boats moving on the surface of the water will observe a Doppler effect for the surface waves. The listener can be in one boat and the other boat can be the source of the waves. For elastic waves propagating below the surface, a Doppler effect will be observed for sources and listeners moving beneath the surface. One example is two submarines, where one produces the elastic waves and the other contains the listener, that detects these waves.

Q16.20 One edge of the star is rotating away from us and the opposite side is rotating toward us. Therefore, the light from the rim of the star at its equator is Doppler shifted and the measured frequency shift can be used to measure the tangential speed *v* at the equator.

Q16.21 What determines the Doppler shift is the component of the train's velocity component along the line between you and the train. This component steadily decreases as the train approaches, is zero as the train passes, and then starts to increase in the opposite direction.

Q16.22 In case 1, the frequency the observer hears is $f_{\text{L1}} = \dfrac{v}{v-u} f_{\text{S}}$, where u is the speed of the source and v is the speed of sound in air. In case 2, the frequency the observer hears is $f_{\text{L2}} = \dfrac{v+u}{v} f_{\text{S}}$, where now u is the speed of the observer and has the same numerical value as u for case 1. f_{L1} is not equal to f_{L2}. The motion of the source affects the wavelength of the observed sound and the motion of the observer affects the speed at which the waves pass the listener. The Doppler shift equation involves the velocity of the observer and the velocity of the source separately, not the relative velocity between the observer and source. The difference between the frequencies for the two cases in this question is $f_{\mathrm{L1}} - f_{\mathrm{L2}} = \dfrac{(u)^2}{v(v-u)} f_{\mathrm{S}}$, The frequency for case 1 is larger than for case 2. But if $u << v$ then the difference in frequencies is very small. For a numerical example, let $v = 340\ \mathrm{m/s}$ and $u = 140\ \mathrm{m/s}$. Then $f_{\mathrm{L1}} = 1.70 f_{\mathrm{S}}$ and $f_{\mathrm{L2}} = 1.41 f_{\mathrm{S}}$.

Q16.23 No, the aircraft continually produces a shock wave as it travels at a speed greater than the speed of sound in the air. An observer on the ground hears the "sonic boom" when this shock wave passes over him.

Q16.24 The air inside the plane is moving with the plane, so sound travels relative to you within the plane with the speed of sound just as it does when the plane is at rest. You don't hear any effect of the shock wave. The sonic boom results from the rapid jump in air pressure when the shock wave passes an observer. The shock wave travels with you so the pressure at your location remains constant.

Q16.25 A sonic boom results from the rapid change in pressure as the edge of the shock wave passes by. A person at *B* hears a sonic boom; observers at *A* and *C* don't.

CHAPTER 17
TEMPERATURE AND HEAT

Discussion Questions

Q17.1 To bring the thermometer to the same temperature as the water heat must flow from the water into the thermometer material. If the thermometer is large compared to the amount of water, this heat flow from the water will change its temperature by a measurable amount. The measurement process would alter, to an unacceptable extent, the quantity being measured.

Q17.2 No. $T_{\text{K}} = T_{\text{C}} + 273.15$. If T_{C} is doubled then T_{K} is less than doubled. For example, if $T = 50°\text{C}$ and then doubled to $100°\text{C}$, T_{K} increases from 323 K to 373 K, and $373/323$ is only 1.15.

Q17.3 The coefficient of volume expansion for aluminum is $7.2\times10^{-5}\ \text{K}^{-1}$ and for steel it is $3.6\times10^{-5}\ \text{K}^{-1}$. So, for a given temperature change the diameter of the aluminum piston will expand more than the inside diameter of the cylinder. If the temperature increase is great enough the piston will expand so much more than the cylinder that it will no longer have room to move freely in the cylinder.

Q17.4 Frozen water pipes burst because water expands when it freezes. Water is unusual in this respect. Most materials contract when they freeze and expand when they melt. This is the case for mercury, so a mercury-in-glass thermometer would not burst if the temperature went below the freezing temperature of mercury.

Q17.5 Hollow cavities expand just like the material that surrounds them. The external dimensions of both objects would increase the same amount.

Q17.6 The diameter of the cap increases when the temperature increases. The diameter of the opening at the top of the bottle also increases with temperature but the coefficient of linear expansion for the bottle material (plastic or glass) is much less than that for the metal cap. And the bottle material is a poor conductor of heat so it takes much longer for its temperature to rise, compared to the cap.

Q17.7 The metallic material of the oven wall is a good conductor of heat and the air is a poor conductor. Also, the mass of a given volume of air is much less than the mass of the same volume of the oven wall, and the heat flow for a given temperature change of an object is proportional to the mass of the object. For both these reasons, much less heat energy flows into your hand when it is in contact with the hot air than when it is in contact with the hot oven wall.

Q17.8 It is incorrect. Two objects with different mc have different thermal energy changes for the same temperature change, so the thermal energy a body contains depends on mc as well as its temperature. And the term heat doesn't mean thermal energy contained in an object; heat is energy transferred due to a temperature difference.

Q17.9 $c = Q/(m\Delta T)$ so the unit for c is $\text{J/(kg}\cdot\text{C}^\circ)$. 1J = 1 $\text{N}\cdot\text{m}$ = 1 $\text{kg}\cdot\text{m}^2/\text{s}^2$ so 1 $\text{J/(kg}\cdot\text{C}^\circ)$ = 1 $\text{m}^2/(\text{s}^2\cdot\text{C}^\circ)$. The student is correct.

Q17.10 When the water changes phase from liquid to vapor, heat energy must flow into it. This heat energy comes out of the air so the air is cooled. The water evaporates more readily if the humidity is high, so such a system works less well in a high-humidity climate.

Q17.11 There is no temperature change associated with a phase change; phase changes occur at constant temperature.

Q17.12 Evaporation of water (sweat) from the skin is an important cooling mechanism for a human body in a hot environment. When the air is dry the evaporation occurs much more rapidly than when the humidity is high.

Q17.13 The product mc is much larger for the potato than for the piece of aluminum foil, due to the small mass of the foil. So, for a given temperature change, much less heat must flow out of the foil than out of the potato. A second reason is that the metal foil is a much better conductor of heat than the potato and therefore heat flows from the foil more readily.

Q17.14 Heat energy flows into the water as it undergoes the phase change associated with evaporation. This heat comes from the water inside the bag and when heat leaves this water, its temperature decreases.

Q17.15 As the water on your skin evaporates heat energy flows from your body into the water.

Q17.16 The body of water has a large value of mc and stores a lot of thermal energy. Heat flows into or out of the water and maintains a more constant temperature of the adjacent land.

Q17.17 Once the water has reached the phase transition temperature of 0°C, additional heat must come out of the water for it to change phase from liquid to solid. Heat flows out more easily for the water next to the metal trays that are in contact with the colder air of the freezer and that are good conductors of heat.

Q17.18 The temperature of your skin is above the boiling point of the alcohol, so it rapidly evaporates. Heat energy goes out of your arm and into the alcohol as it changes phase from liquid to vapor.

Q17.19 The metal is a better conductor of heat so heat flows more readily between your hand and the metal block than between your hand and the wood block when both blocks are at the same temperature. When the blocks have the same temperature as your hand there is no heat flow between them and your hand. So, at this temperature they seem to have the same temperature.

Q17.20 The heat lost by the coffee during the five minutes is proportional to the temperature difference between the coffee and the room. Adding the cream cools the coffee so adding it first lowers the temperature of the coffee at the start of the waiting period and the coffee loses less heat during the five minutes.

Q17.21 The filling has a larger density and specific heat capacity than the crust and is a much better conductor of heat than the crust, so more heat flows from it into your tongue than from an equal volume of crust.

Q17.22 They have large values of mc and are good conductors of heat. Heat from the stove first heats the pot to a uniform temperature.

Q17.23 With its smaller specific heat capacity, the land has a greater temperature change for the same heat flow.

Q17.24 The metal potato nail is a good conductor of heat so conducts heat to the center of the potato. The thermal conductivity of aluminum is four times that of steel, so aluminum nails work better. The water conducts heat along the wick, from the oven to the interior of the meat.

Q17.25 The dark soil of the plowed fields is a better absorber of heat than lighter ground so will be warmer.

Q17.26 We might say this is not correct. The rate of heat conduction does depend on the temperature difference, so the water does cool, for example, more rapidly from 80° C to 79° C than from 20° C to 19° C. But the water must cool to 0° C before it can freeze. So, if you compare water that starts at 20° C to water that starts at 80° C, the 80° C water must first cool to 20° C and after that cools just like the 20° C water cooled initially. The hot water takes longer to freeze. But there are experimental claims that this is not correct, that the hot water does freeze faster. You should do a web search on "hot or cold water in ice cube trays" to read some of the discussion.

Q17.27 The energy emitted by the sun spreads out in all directions so the intensity of sunlight is much less at the surface of the earth than it is at the surface of the sun. H/A is different at the surfaces of the sun and the earth, so by Eq.(17.25) the temperature T is also very different.

Q17.28 This argument does not make sense. The heat energy that must be supplied to the house by its heating system equals the amount of heat lost by the house to the environment. In a full day this heat loss is proportional to the average temperature difference between the house and its surroundings. If the house is kept warm at night this heat loss is greater than if the house is allowed to cool down at night.

CHAPTER 18
THERMAL PROPERTIES OF MATTER

Discussion Questions

Q18.1 The equation of state expressed in Eq.(18.1) shows that in general the volume V depends on the temperature and pressure. An equation of state of this form applies only to a single phase of material, either solid, liquid or gas. Different behavior is found during phase changes.

Q18.2 No, the Celsius temperature could not be used. Converting from Kelvin to Celsius is not done just by multiplying by a conversion factor. You can see that Celsius temperatures can't work because Celsius temperatures can be negative and negative T in Eq.(18.3) doesn't make sense.

Q18.3 The temperature of the air inside the tires increases and this causes the pressure to increase. You should not let air out of the tires to reduce the pressure, they would then be under-inflated when they cool. The recommended inflation pressure for tires are always given as cold-inflation values.

Q18.4 The increase in pressure raises the boiling point of the coolant and prevents it from boiling. If the system were sealed too great of an engine temperature could result in a coolant pressure that would damage engine parts and coolant hoses.

Q18.5 The frozen water in the food undergoes sublimation.

Q18.6 The air pressure at the higher elevation of the slopes was much less than at sea level where the bags were filled and sealed. The pressure difference between the air inside and outside the bags caused them to burst.

Q18.7 At low pressures where the ideal gas law applies the number of atoms per cm^3 is still quite large.

Q18.8 The distribution of speeds of the gas molecules doesn't change when they move through the hole into the other half of the container. Therefore, the total translational kinetic energy of the gas doesn't change and the final temperature will be T_0. The volume doubles and the temperature doesn't change, so $pV = nRT$ says that the pressure is halved. The new pressure is $p_0 / 2$.

Q18.9 (a) A kilogram of each has the same mass. One mole of each has the same number of atoms. The mass of one mole is much larger for lead so one kilogram of lead is fewer moles than one kilogram of hydrogen and therefore has fewer atoms. (b) If we have a mole of hydrogen atoms each has the same number of atoms, equal to Avogadro's number. If we instead have a mole of hydrogen molecules, there are more hydrogen atoms than lead atoms since each hydrogen molecule has two atoms. One mole of lead has more mass than one mole of hydrogen since one lead atom has more mass than either a hydrogen atom or a hydrogen molecule.

Q18.10 (a) Adding heat to the gas increases the average kinetic energy of each gas atom. This increases their average speed and therefore they exert a greater force in collisions with the walls of the container. The increased average speed also means that collisions with the wall are more frequent. (b) Constant temperature means the average kinetic energy of each atom and also the average speed don't change. But with a smaller volume collisions with the walls are more frequent and this increases the average force on the walls.

Q18.11 The mass of a nitrogen molecule is less than the mass of an oxygen molecule so I would expect the proportion of oxygen to be less at higher altitudes, since at a given altitude the gravitational potential energy of an oxygen atom would be greater.

Q18.12 This statement is incorrect. In thermal equilibrium the two gases have the same average kinetic energy per atom. The average speeds will then be inversely proportional to the square root of the masses of the atoms.

Q18.13 The assumption of elastic collisions with the walls in equivalent to assuming that the walls are at the same temperature as the gas. If the walls are hotter or colder than the gas, the gas atoms will gain or lose energy when they collide with the walls.

Q18.14 Temperature is related to the average kinetic energy of the random motion of the atoms. The collective motion of the entire gas does not affect the temperature.

Q18.15 The average translational kinetic energy of one atom of the gas depends on the temperature of the gas. If the volume is also kept constant then the temperature increases when the pressure increases. But if both pressure and volume change such as to keep their product pV constant then the temperature doesn't change and the average translational kinetic energy of the atoms remains constant.

Q18.16 It is justified if the difference in gravitational potential energy of an atom at the top and at the bottom of the container is much smaller than the average kinetic energy of the atoms. Let the container height be h. Then $\Delta U = mgh$. $K_{\text{tr}} = \frac{1}{2}mv_{\text{rms}}^2$. The ratio of these energies is $\Delta U / K_{\text{tr}} = 2gh / v_{\text{rms}}^2$. Example 18.6 shows that $v_{\text{rms}} \approx 500$ m/s so for $h = 1$ m this ratio is very small and neglect of gravitational potential energy changes is justified.

Q18.17 The average speed of the air molecules inside the house would decrease and this would lower the temperature of the air in the house.

Q18.18 The lighter gas atoms have a larger v_{rms} and exit through the hole more frequently.

Q18.19 Eq.(18.14) says that the total average translational kinetic energy of the gas depends on the number of moles and on the Kelvin temperature. For the same total mass, there will be more moles of gas B so specimen B will have more total kinetic energy. We must use the molecular mass of the gas in the analysis.

Q18.20 To double the average translational kinetic energy of each gas atom you must double the Kelvin temperature. 25° C = 298 K and 50° C = 323 K so this temperature does not double the Kelvin temperature. The final temperature would have to be 2(298 K) = 596 K = 323°C to double the average translational kinetic energy per atom.

Q18.21 Eq.(18.19) shows that v_{rms} is directly proportional to the square root of the Kelvin temperature of the gas, so to double v_{rms} the Kelvin temperature T must be increased by a factor of 4.

Q18.22 (a) $Q = nC_V\Delta T$ and $\Delta T = \dfrac{Q}{nC_V}$. C_V is smaller for the monatomic gas so the monatomic gas will increase more in temperature than the diatomic gas. (b) Since the diatomic gas has internal degrees of freedom (rotation and vibration) not all the energy that flows into the gas goes into increasing the translational kinetic energy K_{tr}. Some goes into increasing the rotational and vibrational energy. But only K_{tr} determines the temperature.

Q18.23 No. All ideal diatomic gases have the same molar heat capacity C_V. Therefore, if the same amount of heat flows into 1.00 mol of any diatomic ideal gas, the temperature will increase the same amount. But the number of moles that corresponds to 1.00 g of gas depends on the molecular mass and that will be different for different gases. That is, in $\Delta T = \dfrac{Q}{nC_V}$, C_V will be the same but n will be different and therefore ΔT will be different.

Q18.24 The only thing we can say is that for small Δv the number of molecules having speeds between v and $v + \Delta v$ is $Nf(v)\Delta v$. So, neither statement in the question is correct.

Q18.25 There is no liquid phase below the triple point pressure. Table 18.3 gives the triple point pressure to be 610 Pa for water and 5.17×10^5 Pa for CO_2. The atmospheric pressure is below the triple point pressure of water, and there can be no liquid water on Mars. The same holds true for CO_2. On earth $p_{\text{atm}} = 1.01 \times 10^5$ Pa so on the surface of the earth there can be liquid water but not liquid CO_2.

Q18.26 The water boils when the vapor pressure of the liquid equals the applied pressure, which is being reduced. When the water boils the molecules at the surface with the greatest translational speed escape from the liquid. This reduces the average translational kinetic energy of the molecules remaining in the liquid, and this lowers the temperature of the liquid.

Q18.27 The melting temperature of the ice increases when the applied pressure increases. This is because the volume decreases when ice changes phase to liquid.

Q18.28 The water doesn't boil because the large hydrostatic pressure at this depth increases the boiling point to above this temperature.

Q18.29 Atmospheric pressure on the moon is very small so any liquid water on the surface would boil away.

Q18.30 The boiling point temperature is lower at the lower air pressure at high altitudes. So, the boiling water at high altitudes has a lower temperature.

CHAPTER 19
THE FIRST LAW OF THERMODYNAMICS

Discussion Questions

Q19.1 (a) positive (volume of the gas increases) (b) positive (volume of the gas increases) (c) negative (volume of the gas decreases) (d) negative (volume of the gas decreases).

Q19.2 Heat is transferred from one object to another because of a temperature difference. We can't say that a body contains a certain amount of energy because heat is not a state function; the amount of heat transferred into or out of an object in a process is path dependent.

Q19.3 $W = \int_{V_1}^{V_2} p\ dV$. V_1 and V_2 are the same. When the balloon is inflated the total outward force due to the presence of the air inside the balloon must equal the total inward force due to the pressure of the surrounding air and the force due to the stretching of the balloon material. When the air pressure outside the balloon is less, less pressure inside the balloon is needed to inflate it to a given size. Hence, less work needs to be done to inflate the balloon at the summit of Mt. McKinley.

Q19.4 No, the work and heat transfer are both path dependent. For different paths between the initial and final states the work and heat transfer can be different.

Q19.5 Heat energy enters her body from the chemical processes that metabolize the food. Energy leaves her due to the work of raising herself against gravity and as heat that evaporates her perspiration. If her body temperature rises, this is due to some of the food energy that stays in her body. The first law says energy input = work output + heat output + increase in internal energy. During the descent gravity does positive work on her but she still performs work by the contraction of her muscles. The energy input from the food is again what warms her. During the descent she performs less work and less food energy needs to be inputed.

Q19.6 For a volume decrease $W < 0$. $\Delta U = Q - W$ so $|\Delta U| = |Q| + |W|$; the internal energy change is greater than the heat added.

Q19.7 $\Delta U = Q - W$. If we treat the air inside the balloon as an ideal gas U for the gas depends only on its temperature. During the expansion the temperature increases and ΔU is positive. Therefore, the heat Q added to the balloon is greater than the work done by the air inside it. When the balloon has returned to its original temperature, $\Delta U = 0$. Therefore $Q = W$; the net heat flow to the air equals the net work done.

Q19.8 Since the container is open to the air in the room, the pressure inside the container is constant, always equal to the air pressure in the room. Therefore, the process is isobaric. Heat flows out as the air cools (so the process is not adiabatic), the temperature decreases (so is not isothermal) and the volume of the air that was originally in the container decreases (so not isochoric).

Q19.9 In the expansion the repulsive force between the electrons would do positive work as the electrons move apart. $Q = 0$ and $W > 0$ so $\Delta U < 0$ and the temperature would fall.

Q19.10 $\Delta U = Q - W$. For an adiabatic process $Q = 0$ and $\Delta U = -W$. For an adiabatic process, $p_1 V_1^\gamma = p_2 V_2^\gamma$, where $\gamma > 1$. $V_2 = V_1 \left(\dfrac{p_1}{p_2}\right)^\gamma$. If the pressure decreases, $p_2 < p_1$ and $V_2 > V_1$. For any process, when the volume increases the work W done is positive. Therefore, in this process $W > 0$ and ΔU is negative. The internal energy decreases.

Q19.11 With your mouth wide open there is little expansion work. The air from your lungs is at body temperature so is warmer than the air outside your body (unless you do this experiment in Texas in August!) so feels warm. When you constrict the opening of your mouth the air expands through this opening and is cooled, in an adiabatic expansion.

Q19.12 $\Delta U = Q - W$ so $Q = \Delta U + W$. When the gas expands its volume increases and $W > 0$. $pV = nRT$ says that T increases, since V increases and p is constant. $\Delta U = nC_V \Delta T$ for an ideal gas. Since T increases, ΔU is positive. $Q = \Delta U + W$ and both ΔU and W are positive, so Q is positive.

Q19.13 $\Delta U = Q - W$. Since the container is well-insulated, no heat has been transferred and $Q = 0$. Work has been done <u>on</u> the liquid, so $W < 0$. The force exerted during the stirring moves the liquid in the direction of the force so positive work is done by the stirring force. Irregular stirring increases the force applied to the liquid and thereby increases the work done on the liquid. $\Delta U = -W$ and $W < 0$, so $\Delta U > 0$. The internal energy increases and this corresponds to an increase in temperature of the liquid.

Q19.14 The adiabatic compression of the air in the pump heats the air. $\Delta U = -W$. In the compression $W < 0$ so $\Delta U > 0$. In the adiabatic expansion of the air in the pump cylinder when you raise the handle, the air is cooled. In the expansion $W > 0$ so $\Delta U < 0$.

Q19.15 In the adiabatic expansion of the air it is cooled and can in fact be cooled below 0° C.

Q19 .16 The air in the bubble first expands due to the heat flow into it from the surrounding earth. This initial expansion causes the warmer air in the bubble to be less dense than the surrounding air. The mass of lighter air rises and as it does it cools due to its adiabatic expansion at the lower pressure that exists at the higher altitude. The thermal stops rising when it has cooled to the same temperature as the surrounding air. The expansion of the air bubble is approximately adiabatic because the air rises rapidly. Also, air is a poor conductor of heat so little heat flows out of the air bubble as it expands.

Q19.17 The air does positive work to raise itself against gravity. This is approximately an adiabatic process so $\Delta U = -W$ and for $W > 0$, $\Delta U < 0$ and the air cools.

Q19.18 As the air moves downward on the smooth western slope positive work is done on the air by gravity so $W < 0$. The process is approximately adiabatic so $\Delta U = -W$ and for $W < 0$, $\Delta U > 0$ and the air warms.

Q19.19 By definition $dQ = nC_V\, dT$ for constant volume and $dQ = nC_p\, dT$ for constant pressure. In any process, $dU = dQ - dW$. For constant volume $dW = 0$ and $dU = dQ$. For constant pressure, $dW \neq 0$ and dU is $nC_p\, dT - dW$.

Q19.20 The energy comes from the work done on the gas by the external force that compresses it.

Q19.21 The energy comes from the internal energy of the gas, and that is why the gas cools.

Q19.22 The UF_6 molecule has many more internal degrees of freedom (rotation, vibration) than H_2 does. Therefore, more heat is required for a given temperature change for UF_6 than for H_2, because for UF_6 a larger fraction of the heat added goes into the internal motions of the molecule and less into the translation motion that determines the temperature. Said another way, C_V for the polyatomic molecule UF_6 is larger than C_V for the diatomic molecule H_2 (see Table 19.1), so a given amount of heat flowing into the gas gives a smaller temperature rise for UF_6.

Q19.23 (a) The work done equals the area under the path in the pV-plane. This is greatest for path 1 so the work done by the system is greatest for path 1. It is least for path 3 so the work done by the system is least for path 3. (b) $Q = \Delta U + W$. ΔU is positive and is the same for all three paths so Q is largest when W is largest and this is for path 3. $Q > 0$ and heat is absorbed by the system.

Q19.24 (a) and (b). The magnitude of the work done for each loop equals the area enclosed by the loop and the magnitude of the work done along a path equals the area under the path. For loop I the positive work done while the volume is increasing is larger in magnitude than the negative work done while the volume is decreasing, and the net work done by the system is positive. For loop II the negative work done while the volume is decreasing is larger in magnitude than the positive work done while the volume is increasing and the net work done by the system is negative. The area enclosed by loop I is larger than the area enclosed by loop II so the net work done by the cycle is positive. (c) and (d) For a closed loop, $\Delta U = 0$ and $Q = W$. For loop I W is positive, Q is positive and heat flows into the system. For loop II W is negative, Q is negative and heat flows out of the system. For the complete cycle the net work done is positive so the net heat flow is positive.

CHAPTER 20
THE SECOND LAW OF THERMODYNAMICS

Discussion Questions

Q20.1 The cycle approaches reversibility as the temperature difference between the stove and water approaches zero. In this limit an infinitesimal change in the temperature of the stove can cause the liquid to vapor phase transition to reverse direction.

Q20.2 Reversible: (1) Light, frictionless pulley with a string passing over it and two almost equal masses m_1 and m_2 suspended from the two ends of the string. m_1 descends if it is slightly heavier than m_2 and ascends if m_2 is slightly heavier. A small change in one of the masses causes the system to move in the opposite direction. (2) A block on a horizontal frictionless surface and attached to one end of a spring. The block is pushed against the spring and compresses it. Then the applied force is kept almost equal in magnitude to the spring force. If the applied force is increased slightly the block moves one direction and if the applied force is decreased slightly the block moves back the other direction.

Irreversible: (1) A bullet is fired through a block of wood that is initially at rest on a horizontal frictionless surface. The bullet passes through the block and emerges with reduced speed. Mechanical energy is lost in the collision. The bullet can be sent back through the block by reversing its direction but mechanical energy is again lost in the collision and after the collision the block isn't at rest and the bullet doesn't have the same speed as it did before the original collision.ad (2) A block slides down an incline that has friction. The block has speed v when it reaches the bottom of the incline. If the block is at sent up the incline with initial speed v it won't return to its initial height, due to mechanical energy lost to friction work.

Q20.3 For a refrigerator device, $|Q_\text{H}|=|Q_\text{C}|+|W|$. This says that the heat energy $|Q_\text{H}|$ deposited in the room is the same as the heat energy $|Q_\text{C}|$ removed from the food compartment plus the amount of mechanical energy required to operate the refrigerator (inputed to the device as electrical energy). The tubing is where the heat flows from the device into the room.

Q20.4 The refrigerator operates on a cycle and $Q = W$. $Q = Q_\text{C} + Q_\text{H}$. For a refrigerator $Q_\text{C} > 0$ and $Q_\text{H} < 0$ and $W < 0$, so $|Q_\text{C}| - |Q_\text{H}| = -|W|$. $|Q_\text{H}| = |Q_\text{C}| + |W|$. More heat is delivered to the room than is taken in at the food compartment. Doing this will heat the room. The cooler of ice will cool the room until all the ice is gone. This is not a cyclic process. Heat energy leaves the room and goes into the ice as it changes phase.

Q20.5 For an air conditioner or refrigerator the amount of heat $|Q_\text{H}|$ that flows out of the device is greater than the heat $|Q_\text{C}|$ that flows into the device. In fact, $|Q_\text{H}| = |Q_\text{C}| + |W|$, where $|W|$ is the energy supplied to operate the device. If an air conditioner is set on the floor and plugged in, $|Q_\text{C}|$ is removed from the room but $|Q_\text{H}|$ is ejected into the room. Since $|Q_\text{H}|$ is larger than $|Q_\text{C}|$, the room is heated rather than cooled. A refrigerator also adds heat to the room in which it is placed. That heat must be removed, for example by a window air conditioner, or else the room will be heated.

Q20.6 It is not a violation to convert mechanical energy completely into heat. This is what happens, for example, when a block slides along a horizontal surface and is stopped by friction. The work done by friction converts all of the initial kinetic energy of the block into thermal energy. It is a violation to convert heat completely into work. This would be a 100% efficient heat engine and is prohibited by the second law.

Q20.7 The filter would lower the average speed of air molecules in the house and this would correspond to a lowering of the temperature of that air. The filter would violate the Clausius statement of the second law.

Q20.8 The energy output exceeds the energy input and this violates conservation of energy.

Q20.9 Work is done by the wind and this results in a transfer of heat from the cloth into the surrounding air; the system acts as a refrigerator.

Q20.10 In the Carnot cycle the heat flows occur in isothermal processes with an infinitesimal temperature difference between the working substance of the engine and the reservoir. Therefore, the heat flows occur in reversible processes. For the Otto cycle the heat flows occur in constant volume processes where there is a finite temperature difference between the working substance and the reservoirs. The Carnot cycle is reversible; the Otto cycle is not.

Q20.11 Heat flow in an isolated system is always in the direction from high temperature to low temperature. Work must be supplied to move heat in the opposite direction and more work is needed the greater the temperature difference.

Q20.12 If $T_{\text{C}} = T_{\text{H}}$, $e = 0$. The Carnot engine cannot operate unless the two heat reservoirs are at different temperatures. If $T_{\text{C}} = 0\ \text{K}$, $e = 1$. If the low temperature reservoir were at absolute zero, no waste heat Q_{C} would be deposited there and the Carnot cycle would be 100% efficient.

Q20.13 No. A Carnot cycle is 100% efficient only if $T_{\text{C}} = 0\ \text{K}$, and this is impossible to achieve. Any other cycle would be less efficient.

Q20.14 The room is the high temperature reservoir for the device. The efficiency is lower the greater the temperature of the room. The refrigerator consumes more power when the room temperature is 20°C.

Q20.15 No. 576 J of heat energy is placed into the high temperature reservoir. The net heat flow for the device is $+346\ \text{J} - 576\ \text{J} = -230\ \text{J}$, which means a net flow of 230 J of energy out of the device. But the work done on the refrigerator's working substance puts 230 J of energy into the device and energy is conserved for the device. The heat added to the high temperature reservoir is the sum of the amount of heat taken out of the low temperature reservoir plus the energy added to the system by W.

Q20.16 The change in entropy depends not only on the heat flow but is also inversely proportional to the Kelvin temperature at which that heat flow occurs. The negative heat flow out of the hot object occurs at a higher temperature than the positive heat flow into the cold object, so the positive entropy change is greater than the negative entropy change and the net entropy change is positive.

Q20.17 The mixed water is less organized. In the free expansion the atoms become less confined in space. An increase in thermal energy means more kinetic energy in the random motion of the atoms of the objects. In all these processes the entropy of the system increases.

Q20.18 Eq.(20.19) only applies to a reversible process and the free expansion is not reversible. In a reversible process between the same initial and final states of the gas (an isothermal expansion) there is a heat flow into the gas. And for this process Eq.(20.19) gives the entropy change. Entropy is a state function and the entropy change is path independent. So, the entropy change for the isothermal expansion equals the entropy change for the free expansion and is not zero.

Q20.19 The earth and sun are not in thermal equilibrium; the earth has a much lower temperature than the sun. When heat is transferred from the sun to the earth the energy transfer from the sun occurs at a higher temperature than the energy transfer to the earth. So, the entropy decrease of the sun has a smaller magnitude than the entropy increase of the earth. The total entropy change of the isolated system of the earth plus sun is positive, in agreement with the second law of thermodynamics. Radiation does not differ from other modes of heat transfer with respect to entropy changes.

Q20.20 The first law of thermodynamics is a statement of conservation of energy. If the magnitude of heat that flows out of the cold object equals the amount that flows into the hot object, the first law is satisfied. But this process would violate the second law. For an isolated system (the hot and cold objects) the total entropy would decrease (see Q20.16) in the process and this violates the second law.

Q20.21 You would not see any process that violates conservation of energy or conservation of momentum. These laws still apply when time is reversed. Any irreversible process in which entropy of an isolated system increases will violate the second law of thermodynamics when run in reverse. A simple example is a box sliding along the floor and being stopped by friction. In the real life direction of time kinetic energy is converted entirely into thermal energy. When time is reversed the box moves with increasing speed as thermal energy is converted to kinetic energy. This violates the second law of thermodynamics.

Q20.22 Life forms are not an isolated system. Processes are allowed in which objects have a decrease in entropy, so long as the objects interact with other objects whose entropy increases.

Q20.23 It is not a violation of the second law of thermodynamics because the plant is not an isolated system. The plant receives energy from its environment, from the radiative energy of sunlight.

CHAPTER 21
ELECTRIC CHARGE AND ELECTRIC FIELD

Discussion Questions

Q21.1 When a strip of tape is quickly peeled off the roll, electrons are transferred between the strip and the rest of the roll. Therefore, the two strips have the same sign of net charge and repel. When they are stuck together and then ripped apart, they transfer electrons and end up with net charge of opposite sign and attract each other.

Q21.2 Since they attract, they cannot have net charges of the same sign. Either one is neutral and the other has net positive or negative charge, or one has positive charge and the other has negative charge. After they touch the negative and positive charges neutralize. Any residual net charges spread over the two spheres so they now have charges of the same sign and repel. If there is no residual net charge they don't repel, but in any case they no longer attract.

Q21.3 The charged comb would still pull charges of opposite sign toward it and thereby polarize the charges in the insulator. But the neutral insulator would not be attracted to the comb. The attraction depends on the electric force increasing with decreasing distance.

Q21.4 The tumbling motion in the dryer produces static charges on the clothes and these charges tend not to leak away in the dry air inside the dryer. There will be less clinging if all the clothing is made of the same material; charge is transferred most readily between dissimilar materials. The tumbling of dissimilar materials transfers charge from one material to the other.

Q21.5 The sphere is attracted because its charges become polarized. Negative charge is drawn toward the rod and since the electrical force increases with decreasing distance this causes a net attraction. When the neutral sphere touches the charged rod some of the positive charge of the rod is transferred to the sphere. Now both objects have positive charge and they repel.

Q21.6 Assume that your mass is 70 kg. The mass of an electron is much less than the mass of a proton or neutron. Assume that you have about equal numbers of protons and neutrons, so the total mass of the protons in your body is about 35 kg. The mass of one proton is $1.67\times10^{-27}\ \text{kg}$, so the number of protons in your body is about $\dfrac{35\ \text{kg}}{1.67\times10^{-27}\ \text{kg/proton}} = 2\times10^{28}$. You have neutral charge (or close to neutral) so the number of electrons is 2×10^{28}, equal to the number of protons. The total charge of these electrons is about $(2\times10^{28}\ \text{electrons})(-1.6\times10^{-19}\ \text{C/electron}) = -3\times10^{9}\ \text{C}$.

Q21.7 (a) Electric field points away from positive charge and toward negative charge. So, the top and bottom charges are positive and the middle charge is negative. (b) The electric field is the smallest on the horizontal line through the middle charge, at the two positions on either side where the field lines are least dense. Here the *y*-components of the electric fields of the two positive charges are equal in magnitude and are in opposite directions and the electric field of the negative charge has no *y*-component. Therefore, along this line the *y*-component of the net field is zero. On this line to the right of the charges the *x*-components of the fields of the positive charges are to the right and the *x*-component of the field due to the negative charge is to the left and the *x*-components tend to cancel. On this line to the left of the charges the *y*-component of the net field is again zero and the *x*-components of the positive charges are in opposite directions and tend to cancel.

Q21.8 Both kinds of conduction are due to the free electrons in the conductor.

Q21.9 In Fig.21.28a the field lines are straight lines so the force is always in a straight line and the velocity and acceleration are always in the same direction. The particle moves in a straight line alone a field line, with increasing speed. In fig.21.28b the field lines are curved and the force continually changes direction. As the particle moves, its velocity and acceleration are not in the same direction and the trajectory does not follow a field line.

Q21.10 Place the two objects in contact. Bring a positively charged rod close to one object, on its side opposite the second object. This will pull electrons into the object closest to the rod. With the rod held nearby separate the objects. This will leave one with negative charge and the other with positive charge. The two objects were originally neutral, so the magnitude of the negative charge on one equals the magnitude of the positive charge on the other.

Q21.11 The mass of the book is about 2 kg. Protons and neutrons have about equal masses and their mass is about 2000 times greater than the mass of an electron. There are approximately equal numbers of neutrons and protons so about half the mass of the book (1 kg) is due to protons. The number of protons therefore is about $\frac{1\text{ kg}}{1.67\times 10^{-27}\text{ kg/proton}} = 6\times 10^{26}\text{ protons}$. Assuming equal numbers of electrons and protons there are 6×10^{26} electrons. The net charge if the magnitude of the charge of an electron is $1.00\times 10^{-3}\%$ less than that of a proton is $\Delta q = (1.00\times 10^{-5})(1.6\times 10^{-19}\text{ C})(6\times 10^{26}) = 960\text{ C}$. The textbook would have a charge of about 1000 C. The repulsive force between two textbooks placed 5 m apart would be about $(9\times 10^{9}\text{ N}\bullet\text{m}^2/\text{C}^2)(1000\text{ C})^2/(5\text{ m})^2 = 4\times 10^{14}\text{ N}$. This is an immense force. Even the slightest difference in the proton charge and the magnitude of the electron charge would result in explosive repulsion.

Q21.12 It is easier for charge to build up on you when the air is dry. Humid air conducts the charge from your body. There is more space for net charge on a large object, so a large object can accept more charge.

Q21.13 Charging by touching transfers charge of the same sign to another object. Using a charged object to charge another object by induction places charge of the opposite sign on the second object.

Q21.14 The acceleration of the charge depends on the electric force exerted on it by the other charge. This force is given by $F = k\frac{q^2}{r^2}$. The force at the instant the charge is released depends only on the distance between the two charges and is the same whether the other charge is free to move or is held fixed in place.

Q21.15 The force on each charge has magnitude $F = k\frac{Q(2Q)}{r^2}$. The same magnitude of force acts on each charge and the charges have the same mass. Therefore, the charges will have initial accelerations of the same magnitude.

Q21.16 The two particles have charges of the same magnitude and opposite sign. The electric field exerts forces of the same magnitude and opposite direction on the two particles. They have different masses, so the accelerations are of different magnitude, with the electron's acceleration being larger. The acceleration of the proton is in the direction of the electric field and the acceleration of the electron is opposite to the direction of the electric field.

Q21.17 The earth contains an immense number of electrons and protons, but in equal numbers so it is electrically neutral and exerts no electrical force on other objects. The mass of the earth is very large so the gravitational force it exerts is large.

Q21.18 They both occur between pairs of objects. They both are inversely proportional to the square of the distance between the objects. All objects have mass and exert a gravitational force on each other. Only objects with net charge exert an electrical force. The gravitational force is always attractive but the electrical force can be either attractive or repulsive depending on whether the two objects have charges of the opposite or of the same sign.

Q21.19 (a) Electric field points away from positive charge and toward negative charge so object *B* has positive charge and object *A* has negative charge. (b) The electric field lines are closer together near object *A* so the field is stronger near object *A*.

Q21.20 If the only forces were the electrical and gravitational forces, the gravitational force wouldn't be strong enough to overcome the electrical repulsion of the protons and the nucleus would be unstable. The protons and neutrons are all bound together by a nuclear force.

Q21.21 The electric field exerts a force on the electrons, according to Eq.(21.3). If the force from the external electric field is stronger than the forces that bind the electron to the atom, the force from the field can pull electrons from the atom.

Q21.22 No. Field lines for the resultant field due to the set of charges never cross. But $\vec{E}_1$ and $\vec{E}_2$ are the electric fields of individual charges and it is their vector sum that determines the direction of the field line at point *P*.

Q21.23 Air velocity is a vector field because velocity is a vector. Temperature is not a vector field because temperature is a scalar, not a vector.

CHAPTER 22
GAUSS'S LAW

Discussion Questions

Q22.1 The total flux through the balloon is q/ϵ_0, regardless of the size of the balloon.

Q22.2 The flux through each surface is equal to $\dfrac{Q_{\text{encl}}}{\varepsilon_0}$, where Q_{encl} is the net charge enclosed by the surface. Surface *A*: $Q_{\text{encl}} = +q$ and $\Phi_{EA} = +q/\varepsilon_0$. Surface *B*: $Q_{\text{encl}} = +q$ and $\Phi_{EB} = +q/\varepsilon_0$. Surface *C*: $Q_{\text{encl}} = +2q$ and $\Phi_{EC} = +2q/\varepsilon_0$. Surface *D*: $Q_{\text{encl}} = 0$ and $\Phi_{ED} = 0$.

Q22.3 The electric flux through a surface depends only on the charge within the surface. The net flux through the surface due to charges outside the surface is zero. The total flux through each of these surfaces would remain the same.

Q22.4 The electric field doesn't need to be zero on the surface, only the total electric flux through the surface needs to be zero. The electric field would be zero everywhere on the surface, for example, if the surface was totally in the material of a conductor.

Q22.5 The electric field is inversely proportional to the square of the distance from the point charge, so the field at each point on the surface changes. Gauss's law says that the total flux through a closed surface depends only on the net charge enclosed by the surface and that hasn't changed, so the total flux doesn't change. All the field lines from the point charge still pass outward through the surface.

Q22.6 Measure the electric field flux through a Gaussian surface that encloses the box. The total flux through the surface is nonzero if and only if there is no net charge in the box.

Q22.7 The electric field inside the conductor is still zero. The point charge polarizes the charge on the surface of the sphere such that the electric field of the surface charge exactly cancels the electric field of the point charge at all points within the sphere. The net charge on the sphere is still on its surface. But this charge is not distributed uniformly over the surface of the sphere. There is more positive charge in the area near the negative point charge, because the negative point charge pushes away electrons on the sphere.

Q22.8 Gauss's law would not be valid. For a Gaussian sphere of radius r with a point charge at the center, the electric field at the surface would be proportional to $1/r^3$. The area of the sphere is proportional to r^2, so the total flux through the sphere will be proportional to $1/r$ and will depend on the radius of the sphere.

Q22.9 No. These free electrons aren't excess charges; their negative charge is exactly balanced by the positive charge of the ions in the material.

Q22.10 Negative charge on the sphere is pulled toward the van de Graff generator and this leaves positive charge on the side of the sphere that is farthest from the generator. The sphere has zero net charge. For a Gaussian surface that lies just outside the surface of the sphere the enclosed charge is $Q_{\text{encl}} = 0$. Therefore, Gauss's law says the net flux through the sphere is zero. Any Gaussian surface that is entirely inside the sphere encloses zero charge and the electric field inside the sphere is zero.

Q22.11 Lightning is a flow of electrons. The lightning current runs through the copper cables since copper is a good conductor of electricity whereas the house material is not. The rods are pointed because the electric field is strong there when the rod gains some charge. The strong electric field ionizes the air near the sharp point and provides a conducting path.

Q22.12 A point charge affects the electric field outside the conductor. The point charge induces a charge of equal magnitude and opposite sign on the inner surface of the conductor. The conductor is overall neutral so there is a charge equal to the point charge spread over the exterior surface of the conductor. This exterior charge produces an electric field outside the conductor. Charge outside the conductor doesn't produce any electric field inside the cavity. The electric field of the external charge is shielded by the conductor.

Q22.13 A component of field parallel to the surface would exert a force on the free electrons in the conductor and cause them to move. In an insulator there are no charges free to move and there is no reason why the electric field at the surface of an insulator can't have a component parallel to the surface.

Q22.14 (a) Consider a small Gaussian surface somewhere in the region. Since the electric field is uniform the flux through the surface must be zero. Therefore, the enclosed charge $Q_{\text{encl}} = \int \rho \, dV$ must be zero. But since this must be true for any volume in the region, $\rho = 0$ everywhere in the region. (b) No. For example, consider the region near a point charge. There is no charge there but the electric field, which is due to the nearby point charge, is not uniform.

Q22.15 (a) If $\rho > 0$ and uniform, then the charge inside any closed surface is greater than zero. Therefore, $\Phi_E > 0$ for any Gaussian surface. But if the field is uniform then $\Phi_E = 0$ for any Gaussian surface, so the field can't be uniform. (b) Yes. The flux through the surface of the bubble must be zero but that is true for a uniform field within the bubble, so that kind of field is allowed. (See Problem 22.57.)

Q22.16 Apply Gauss's law to a Gaussian surface that lies entirely within the metal. $E = 0$ at all points within the meal conductor so the flux through this surface is zero. By Gauss's law the Gaussian surface must enclose zero net charge. This means that there is net charge $+Q$ on the inner surface of the metal. Since the solid is grounded there is no excess charge on the outer surface of the metal. Any excess charge there would be neutralized by charge from the earth. A gaussian surface entirely outside the piece of metal would enclose zero net charge ($-Q$ from the charge in the cavity plus $+Q$ on the inner surface of the metal). The flux through the surface, for any shape, would be zero so the electric field at all points outside the piece of metal is zero. It is reasonable to say the grounded conductor has shielded the region outside the conductor from the effects of the charge $-Q$. There is nothing like positive and negative mass (the gravity force is always attractive), so this cannot be done for gravity.

CHAPTER 23
ELECTRIC POTENTIAL

Discussion Questions

Q23.1 The concept of potential is useful for the same reason that electric field is useful. It allows us to calculate the effect of the source charges on the space surrounding them. A test charge then has electrical potential energy when placed in the potential of the source charges. And electric potential will prove to be a very useful concept for analyzing electrical circuits.

Q23.2 Yes, just bring the test charge in along the perpendicular bisector of the line that connects the two charges. The electric potential is zero at all points along this line, since all points on the line are equidistant from the two charges. There is no change in potential along the line so no work is done on the test charge anywhere along the line. The two charges produce a net electric field along this line, but at all points on the line the electric field has no component parallel to the line. So the electric force does no work on a test charge moving along this line.

Q23.3 If the potential where the two charges are infinitely far apart is taken to be zero, then the electric potential energy of the pair is $U = kq_1q_2/r$. Only for $r \to \infty$ is this zero, so it is not possible for two charges. For three charges not all of the same sign it is possible. You need just to arrange the separations of the three charges 1, 2, and 3 such that $U_{12} + U_{23} + U_{13} = 0$.

Q23.4 The voltmeter reads the potential difference between the two points to which it is connected. The potential difference between two points is independent of the choice for the reference level of zero potential.

Q23.5 If $E = 0$ along the path then the work done by the electric force on a test charge as it moves along this path is zero. Eq.(23.13) then says that $V_A = V_B$. $\vec{E}$ does not have to be zero everywhere along other paths connecting A and B, but the work done by $\vec{E}$ on a test charge must be zero along any of these paths. This is because the electric force is a conservative force and the work it does is path independent.

Q23.6 Eq.(23.17) says that V is constant throughout this region but it isn't necessarily zero.

Q23.7 Electric field lines point away from positive charge and toward negative charge. Potential is large and positive near positive charge and low (large in magnitude and negative) near negative charge. Therefore, electric fields are always in the direction of lower potential; electric-field lines point from high to low potential. For another way to show this, consider a positive test charge q that moves from point a to point b. $\frac{W_{a\to b}}{q} = V_a - V_b$, where $W_{a\to b}$ is the work done on charge q by the electric field in which it moves. If the electric field is in the direction from a to b, then the direction of the force on q is from a to b and this force does positive work. $\frac{W_{a\to b}}{q}$ then is positive and $V_a - V_b$ is positive. Therefore, $V_a > V_b$ and the electric field direction is the direction of decreasing potential.

Q23.8 (a) No. At a point midway between two point charges of equal magnitude and opposite sign the potential (relative to infinity) is zero but the electric field is not zero. The electric field is directed toward the negative charge. (b) No. At a point midway between two equal point charges (equal in magnitude and sign) the electric field is zero and the potential (relative to infinity) is not zero. The potential depends on the electric field along a path from infinity to the point, not just on the electric field at the point.

Q23.9 The electric force is conservative so the work it does is path independent and is zero for any closed path. By Eq.(23.17) the integral $\int \vec{\boldsymbol{E}} \cdot d\vec{\boldsymbol{l}}$ from point a to point b equals $V_a - V_b$. But when a and b are the same point the potential difference is necessarily zero so the integral $\int \vec{\boldsymbol{E}} \cdot d\vec{\boldsymbol{l}}$ completely around a closed path must be zero.

Q23.10 If they are placed negative terminal to positive terminal, the potential increases by 3.0 V in going from the negative terminal of the first to the positive terminal of the second. If they are placed positive terminal to positive terminal, the potential rises 1.5 V across one battery and decreases 1.5 V across the second one so the potential difference between the terminals of the exposed ends is zero.

Q23.11 The static charge on your body is at very high potential but the amount of net charge is very small so the potential energy of that charge is small. The power line is capable of delivering a much larger amount of electrical energy because much more charge flows from it.

Q23.12 Eq.(23.20) shows that $\vec{\boldsymbol{E}}$ is determined by the change with distance of $V(\vec{\boldsymbol{r}})$. V at a single point tells us nothing about $\vec{\boldsymbol{E}}$.

Q23.13 There is no ambiguity because $E = 0$ at this point and therefore has no direction.

Q23.14 $V_a - V_b = \int_a^b \vec{\boldsymbol{E}} \bullet d\vec{\boldsymbol{l}}$. If the direction from a to b is the same as the direction of $\vec{\boldsymbol{E}}$, then the integral is positive and $V_a > V_b$. Therefore, the electric field always points toward lower potential. In a direction perpendicular to the electric field the potential is constant since in that case $\vec{\boldsymbol{E}}$ and $d\vec{\boldsymbol{l}}$ are perpendicular and $\vec{\boldsymbol{E}} \bullet d\vec{\boldsymbol{l}} = 0$. Therefore $V_B > V_A$, $V_C < V_A$ and $V_D = V_A$

Q23.15 No. At a point one meter from an isolated positive point charge the electric potential is positive but there is no charge at this point. At a point one meter from an isolated negative point charge the electric potential is negative but there is no charge at this point. For both these examples we are taking $V = 0$ at an infinite distance from the point charge. The choice of zero potential determines whether a particular point has positive or negative potential, and this choice is arbitrary.

Q23.16 Consider charge dq added to the sphere after it already has charge q. The potential of the surface of the sphere at this point in the charging process is $V = kq/R$, where R is the radius of the sphere. The potential energy of dq when it is placed on the sphere is then $dU = V\,dq = kq\,dq/R$. The total potential energy of the charged sphere is

$$U = \int_0^Q \frac{kq\,dq}{R} = \frac{kQ^2}{2R}.$$

Q23.17 It doesn't matter. Any convenient choice can be made for what equipotential we call $V = 0$.

Q23.18 The electric field inside the sphere is zero, no matter where the sphere is placed and no matter whether the sphere has a net charge or not. In electrostatics, the electric field within a conductor is always zero. All points of the sphere are at the same potential, but the value of this potential depends on how far the sphere is from the positively charged plate. This is true whether the sphere has net charge or not.

Q23.19 The electric field is zero in the conductor and in the cavity, so the potential is constant in these regions. The potential in the cavity equals the potential in the material of the conductor.

Q23.20 The body of the car and its interior are both at the same potential so people inside the car are unaffected. The potential difference between the car and the ground is 10,000 V so when a person steps out this potential difference appears between their foot on the ground and the part of them still in contact with the car and a very dangerous current flows through them.

Q23.21 The static electricity in the atmosphere can place a net charge on the ship. The light appears when this charge discharges into the air. The electric field E is largest near sharp points so this is where the discharge occurs. The seawater on the wet masts conducts the charge to the discharge point.

Q23.22 This is true and is an example of the "image charge" method often used in solving certain electrostatic problems. In Fig.23.23b, the electric field lines are symmetric about the $V = 0$ line that runs between them and would be perpendicular to a plane running along this line and consisting of points equidistant from the two charges. The electric field is perpendicular to a conducting surface so the field lines in half the figure would be unchanged by replacing one of the charges by a conducting surface at this plane.

CHAPTER 24
CAPACITANCE AND DIELECTRICS

Discussion Questions

Q24.1 $E = V/d$ so for a given potential V across the capacitor E becomes larger as d is decreased. When E exceeds the dielectric strength of whatever is between the plates of the capacitor, current flows through the dielectric and the capacitor discharges.

Q24.2 The electric field between the plates is proportional to the surface charge density σ on the plates: $E = \dfrac{\sigma}{\varepsilon_0}$. The potential difference between the two plates is related to the electric field between the plates by $V_{ab} = Ed$. Capacitance is defined as $\dfrac{Q}{V_{ab}}$. The greater the area of the plates the smaller the surface charge density for a given *Q*. So, with greater area the capacitor can hold more charge for the same *E* and *V* and this makes *C* larger. Increasing the separation between the plates increases V_{ab} for the same *E* and hence the same *Q*. Increasing V_{ab} decreases *C*.

Q24.3 Due to the attraction of the opposite charges on the plates, charge will be on only that part of the larger plate that is directly across from the smaller plate. Both the capacitor and the battery remain neutral; the two plates have charges of equal magnitude.

Q24.4 The magnitude of charge Q on each plate of the capacitor is given by $Q = CV$. More charge is stored when C is larger. $C = \dfrac{\varepsilon_0 A}{d}$ so C is larger when d is smaller. It is better to have the plates closer together.

Q24.5 (a) No. This is true only when d is much smaller than the dimensions of the plates. (b) The electric field is no longer confined to the region between the plates so the force on a charge between the plates is less than it would be if the field was confined between the plates. The smaller force does less work on a test charge that moves from one plate to the other so the potential difference is less than given by $V_{ab} = Qd/\epsilon_0 A$ since this equation assumes the field is confined to the region between the plates. (c) $C = Q/V$ so smaller V means larger C.

Q24.6 The battery keeps the potential V between the plates constant. $E = V/d$ so when the separation d is doubled the electric field is halved. $C = \epsilon_0 A/d$ so the capacitance is halved and by $Q = CV$ the charge Q on the plates is halved. Less charge is needed to produce the same potential difference when the separation is doubled. $U = \tfrac{1}{2}QV$ so the energy stored in the capacitor is halved.

Q24.7 Since the capacitor is disconnected from the battery, the charge on its plates remains constant. $E = Q/A\epsilon_0$ so E is unchanged. $V = Ed$ so V doubles. $U = \tfrac{1}{2}QV$ so the total energy stored is doubled. The energy increase comes from the work done in pulling the plates farther apart.

Q24.8 The two capacitors have the same *V*. Let capacitor 1 have plate separation *d* and capacitor 2 have plate separation $2d$. $C = \dfrac{\varepsilon_0 A}{d}$, so $C_1 = 2C_2$. $Q = CV$ so $Q_1 = 2Q_2$. $E = \dfrac{\sigma}{\varepsilon_0} = \dfrac{Q}{A\varepsilon_0}$ so $E_1 = 2E_2$. The energy density is $u = \tfrac{1}{2}\varepsilon_0 E^2$ so $u_1 = 4u_2$. The capacitor with the smaller plate separation has the stronger electric field, the greater charge and the greater energy density. This capacitor needs more charge to produce the same potential difference between its plates.

Q24.9 See Q24.7. The energy added is stored in the capacitor. The electric field stays the same so the energy density is the same. But the volume occupied by the field increases and the total energy stored by the field increases.

Q24.10 The stored energy for a capacitor is given by $U = \frac{1}{2}CV^2$. In parallel the potential difference V across each capacitor equals the battery voltage whereas in series the potentials add to give the battery voltage. Therefore, the voltage for each capacitor is greater in parallel and the stored energy is greater when they are connected in parallel.

Q24.11 Water is an excellent solvent and would tend to dissolve or corrode the capacitor plates. Also, it conducts current if it contains dissolved ions and isn't perfectly pure.

Q24.12 No, they are different. Dielectric strength is the largest the electric field can be before the dielectric becomes conducting. The dielectric constant K is a measure of the extent to which charge polarization in the dielectric cancels the electric field due to the charges on the plates. The presence of the dielectric between the plates increases the capacitance by a factor of K. In Table 24.2 there is no relationship evident between dielectric strength and dielectric constant.

Q24.13 The holes are places where Mylar is replaced by air. The area of the holes is a small fraction of the total area of the charged conductors so the presence of the air makes little difference to the average electric field between the plates. But the dielectric strength of air is much less than that of Mylar and breakdown at the holes occurs when the dielectric strength of air is exceeded.

Q24.14 The surface of the dielectric closest to the positively charged plate has a negative induced charge and the surface of the dielectric closest to the negatively charged plate has a positive induced charge. The plates of the capacitor therefore exert an attractive force on the dielectric and this force does positive work on the slab as it moves into the region between the two plates. $W_{a\to b} = U_a - U_b$ so when the force does positive work the potential energy associated with that force decreases. Therefore, less energy is stored in the capacitor after the dielectric has been inserted. We can see this from $U = \dfrac{Q^2}{2C}$. Q is constant and C increases ($C = KC_0$), so U decreases.

Q24.15 The capacitance depends on the dielectric constant of the fish and this in turn depends on the amount of water in the fish's tissue.

Q24.16 It is much easier to achieve a small and uniform separation between the two conductors.

Q24.17 The flux decreases by a factor of $1/K$ since the enclosed charge decreases by a factor of $1/K$. Without the dielectric the enclosed charge is σA and the electric flux through the surface is $\sigma A/\varepsilon_0$. With the dielectric present the enclosed charge is $(\sigma - \sigma_{\text{i}})A$. But $\sigma_{\text{i}} = \sigma(1 - 1/K)$ so $(\sigma - \sigma_{\text{i}})A = \dfrac{\sigma A}{K}$ and the electric flux through the surface is $\sigma A/\varepsilon_0 K$.

Q24.18 The one fact that is always true is that $C = KC_0$, where C_0 is the capacitance without the dielectric and C is the capacitance with the dielectric.
Power supply keeps the voltage V constant:
(i) $E = V/d$. V is constant so E doesn't change.
(ii) $Q = CV$. C increases so Q increases.
(iii) Use $U = \frac{1}{2}CV^2$. V is constant and C increases so U increases.
Charge Q kept constant:

(i) $V = Q/C$. Q is constant and C increases, so V decreases. $E = V/d$ so E decreases.

(ii) Q is constant.

(iii) Use $U = Q^2/2C$. C increases and Q is constant so U decreases.

Q24.19 Increasing temperature increases the kinetic energy of the molecules and this decreases the alignment of their molecular dipoles. This decreases the electric field they produce that opposes the electric field due to the charges on the plates.

Q24.20 If Q is kept fixed, $E = E_0/K$. The dielectric constant is a measure of the extent to which the polarization of the dielectric decreases the electric field between the capacitor plates. The greater the cancelation of the field, the larger the dielectric constant. For a conductor the induced charges totally cancel the electric field, the electric field in the conductor is zero. This corresponds to $K \to \infty$.

Q24.21 The oil has dielectric constant $K > 1.0$. A charge separation in the oil produces an electric field that partially cancels the electric field due to the charge on the plates, so the electric field between the plates decreases. The net electric field between the plates could be measured by measuring the force on a test charge placed in the oil between the plates.

CHAPTER 25
CURRENT, RESISTANCE AND ELECTROMOTIVE FORCE

Discussion Questions

Q25.1 No. The statement in Chapter 21 refers to an electrostatic situation where there is no movement of charge. $\rho = E/J$ refers to a situation where current is flowing in the conductor, so charges are moving.

Q25.2 $R = \dfrac{\rho L}{A} = \dfrac{\rho L}{\left(\pi D^2/2\right)}$, where L is the length and D is the diameter. $L' = 3L$ and $D' = 3D$ gives $R' = \dfrac{\rho L'}{\left(\pi [D']^2/2\right)} = \dfrac{\rho(3L)}{\left(\pi [3D]^2/2\right)} = \dfrac{3}{9}\dfrac{\rho L}{\left(\pi D^2/2\right)} = \dfrac{1}{3}R$.

Q25.3 The resistivity ρ is a property of the material of which the resistor is made and does not depend on the size or shape of the resistor. The resistivity remains ρ.

Q25.4 $v_{\rm d} = J/(nq) = I/(nqA)$. The current I, by conservation of charge, is the same in both wires. For smaller cross sectional area the current density increases and the drift speed increases. By Eq.(25.5) the larger current density means the electric field is larger in the smaller wire. The increased electric field provides the force that accelerates the electrons to a higher drift speed.

Q25.5 When current is flowing through the battery in the direction from the negative terminal toward the positive terminal the terminal voltage is $V = \mathcal{E} - Ir$. The emf is $\mathcal{E} = 1.5\ \text{V}$ and V_{ab} is less than this.

Q25.6 Yes. If current is being pushed through the battery from the $-$ to the $+$ terminal by another voltage source, as shown in Fig. DQ25.6. The voltage drop Ir across the internal resistance of the battery is directed opposite to the emf. If this current is large enough the potential of the + terminal of the battery can be lower than the potential of the $-$ terminal; $V_a < V_b$.

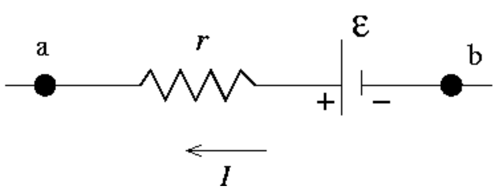

Figure DQ25.6

Q25.7 Yes. The open-circuit voltage is $\mathcal{E}$. The short-circuit current is $I = \mathcal{E}/r$ so $r = \mathcal{E}/I$.

Q25.8 No. The current the battery provides depends on the total resistance of the circuit connected across the battery terminal. The current depends not only on the battery but also on the rest of the circuit.

Q25.9 A wire carrying a current of 10 A remains electrically neutral. But a huge amount of charge (10 C) passes a cross section of the wire each second.

Q25.10 (a) The current is the same on both sides of the resistor so the current density is the same. $v_{\rm d} = J/(nq)$ so the drift speed is the same on both sides of the resistor. (b) The electric potential V

is higher at the end of the resistor when the conventional current enters. Electrons move opposite to the direction of the conventional current so move to higher potential. Negative charge loses potential energy when it goes to higher potential. Electrons lose electrical potential energy when they pass through the resistor.

Q25.11 (a) For a resistor $P = \frac{V^2}{R}$. When the temperature increases the resistance of the copper heating element increases. Since V is constant, the electrical power consumed by the resistor decreases. (b) For carbon the temperature coefficient of resistivity α is negative (Table 25.2) and the resistance of the carbon cylinder decreases when its temperature increases. Therefore, the electrical power it consumes increases. It is a general rule that the resistance of a metallic conductor, like copper, increases as the temperature increases. And the resistance of a semiconductor (carbon is an example) decreases as its temperature increases.

Q25.12 If the resistor is made of a metal its resistance increases with temperature, and the greater the current the greater the temperature of the resistor. Ohm's law says $I = V / R$ and a graph if I versus V is a line with slope $1/R$. But since R increases when V and I increase, the slope decreases as V increases. This behavior corresponds to graph (d).

Q25.13 Resistance increases with temperature so the current through the bulb decreases when the bulb heats up. Current through the bulb is largest when the light is first turned on.

Q25.14 In (a) the same current flows through each bulb and they have equal brightness. In (b) the resistance is halved so the current is doubled compared to (a) and bulb A is brighter.

Q25.15 (a) In both circuits the same current flows through the ammeter. The current is the same everywhere in the circuit, current doesn't get "used up" when it passes through the bulb. (b) Since the current through the bulb is the same in both circuits the bulb is the same brightness.

Q25.16 An ideal ammeter is a very low resistance device and does not add resistance to the circuit. An ideal voltmeter is a very high resistance device and adds a very large resistance in series with the light bulb. In (b) the total circuit resistance is very large and the current through the bulb is very small. The bulb will be much brighter in (a).

Q25.17 In both the charging process and when the battery delivers energy to a circuit some energy is lost to thermal energy as the current flows through the internal resistance of the battery.

Q25.18 No, their internal resistance is too high. They wouldn't be able to supply enough current to start the car.

Q25.19 The electrical energy delivered to a device is $P = VI$. Larger V means smaller I. Energy loss in the wires occurs at a rate I^2R so if I is smaller R can be larger and the circuit still have the same rate of energy loss in the wires. Thinner wires have larger R.

Q25.20 The electrical energy delivered to a device is $P = VI$. Larger V means smaller I. Energy loss in the wires occurs at a rate I^2R so if I is smaller then there is less energy loss due to the resistance of the transmission lines. A disadvantage is the danger of high voltages and the need to step up and step down the voltage before and after transmission.

Q25.21 The voltage of the electrical system in each case is matched to the power that must be delivered to the devices in the system. The lower voltage in an automobile system requires higher currents but the electrical transmission distances are small so losses due to wire resistance is tolerable. Also, the lower voltage auto system is safer. It is more common for untrained people to poke around under the hood of a car than to get involved in their household wiring.

Q25.22 It should have low resistance and a melting point of the desired value.

Q25.23 The larger internal resistance limits the short-circuit current.

Q25.24 The energy transported by the electrical current is much larger than the heat energy conducted in the opposite direction. The potential difference drives the electrons in one direction. To conduct heat they would have to travel in the opposite direction.

CHAPTER 26
DIRECT CURRENT CIRCUITS

Discussion Questions

Q26.1 $P = V^2 / R$ so the bulb with larger P has smaller R; the resistance of the 120-W bulb is smaller. $V = IR$ and in series the current is the same through each, so the 60-W bulb has a greater voltage drop. In parallel the voltages across each bulb will be the same.

Q26.2 The 25-W bulb has a larger resistance than the 200-W bulb (see Q26.1). In series the currents are the same so the voltage drop across the 25-W bulb is larger than that across the 200-W bulb. The voltage drops add to 240 V so the voltage across the 25-W bulb is larger than 120 V and the 25-W bulb is the one that burns out quickly. When the voltage across it is greater than 120 V it dissipates more than 25 W.

Q26.3 (i) series: More bulbs in series add to the total resistance of the circuit and this decreases the current. The brightness of each bulb decreases as bulbs are added in series. (ii) parallel: The full battery voltage is placed across each bulb in parallel, no matter how many bulbs there are. The brightness of each bulb is the same as more are added in parallel, if the internal resistance of the battery can be neglected.
In series the current through the battery is $I_s = \mathcal{E} / R_T = \mathcal{E} / (nR)$ for n bulbs of resistance R. In parallel the current through the battery is $I_p = n(\mathcal{E} / R)$. $I_p = n^2 I_s$. The total power delivered by the battery is $\mathcal{E} I$ so the power is greater by a factor of n^2 when the bulbs are connected in parallel. The battery lasts longer when the bulbs are in series.

Q26.4 The voltage across A is $\mathcal{E}$ and the voltage is $\mathcal{E} / 2$ across B and C. A has more current through it, more potential difference across it and is the brightest. If A is unscrewed the voltages across B and C don't change and the brightness of B and C don't change. If B is unscrewed there is no current path in that parallel branch and C goes out. The voltages across A is still $\mathcal{E}$ and the brightness of A doesn't change.

Q26.5 (a) True. For resistors in series the current is the same in each resistor. The reason is conservation of charge. All the charge that flows through R_1 as I_1 must also flow through R_2 as I_2. The current entering a resistor always equals the current leaving the resistor. (b) False. (c) False. $P = I^2 R$ so $P_1 = I_1^2 R_1$ and $P_2 = I_2^2 R_2$. $I_1 = I_2$ and $R_2 > R_1$ means that $P_2 > P_1$. (d) True.
(e) False. $V_1 = I_1 R_1$ and $V_2 = I_2 R_2$. $I_1 = I_2$ and $R_2 > R_1$ so $V_2 > V_1$. (f) False. IR is the potential drop across a resistor. The end of the resistor where the current enters is at higher potential than the end where the current exits. $V_a > V_b$ and $V_b > V_c$. (g) False. (h) True.

Q26.6 (a) False. $V_1 = V_2$ so $I_1 R_1 = I_2 R_2$. $I_2 = I_1 \dfrac{R_1}{R_2}$. $R_2 > R_1$ so $I_2 < I_1$. (b) True. At point *a* the current I_3 splits into I_1 and I_2. At *b*, I_1 and I_2 combine to form I_4. Conservation of charge says $I_3 = I_4$. (c) True. (d) False. $P = \dfrac{V^2}{R}$. $P_1 = \dfrac{V_1^2}{R_1}$ and $P_2 = \dfrac{V_2^2}{R_2}$. Since $V_1 = V_2$ and $R_2 > R_1$, then $P_1 > P_2$. (e) False. (f) True. Points *a*, *c* and *e* are all at the same potential and points *d*, *f* and *b* are all at the same potential. (g) True. The potential difference between the ends of R_1 is $I_1 R_1$ and the end where the current enters is at higher potential. (h) False. (i) False.

Q26.7 Since the battery has no internal resistance its terminal voltage is independent of the current through it and is equal to its emf $\mathcal{E}$. Closing the switch adds a third bulb in parallel to the other two. But the voltage across each bulb is $\mathcal{E}$ and doesn't change when the third bulb is connected. The brightness of bulbs B_1 and B_2 won't change.

Q26.8 Decrease. The resistor is equivalent to three resistors in parallel. Adding resistors in parallel decreases the total resistance so cutting one of the strips and therefore changing from three resistors in parallel to two in parallel increases the overall resistance. Before the strip is cut, $R_{\text{equiv}} = \frac{R}{3}$. After the strip is cut, $R_{\text{equiv}} = \frac{R}{2}$. Since the resistance increases the current through the ammeter decreases.

Q26.9 Increase. Closing the switch adds another resistor in parallel to the resistor network and this reduces the resistance of the network and thereby the total resistance of the circuit. This increases the current through the light bulb.

Q26.10 Decreases. The voltage across the light bulb equals the terminal voltage of the battery. When the switch is closed the total equivalent resistance of the circuit decreases and the current through the battery increases. An increase in current through the battery causes the terminal voltage to decrease and the current through the light bulb decreases.

Q26.11 Won't change. Since the battery has no internal resistance its terminal voltage equals its emf, independent of the current through the battery. The voltage across the bulb equals the terminal voltage of the battery, independent of whether the switch is open or closed. The current through the bulb doesn't change when the switch is closed.

Q26.12 (a) Don't change. Since the battery has no internal resistance its terminal voltage equals its emf, independent of the current through the battery. The voltage across the branches containing the bulbs equals the terminal voltage of the battery, independent of whether the switch is open or closed. The currents through the bulbs don't change when the switch is closed. (b) Decrease. Now when the switch is closed and the current through the battery increases, the terminal voltage of the battery decreases.

Q26.13 Yes, it is possible. An example is shown in Fig. DQ26.13.

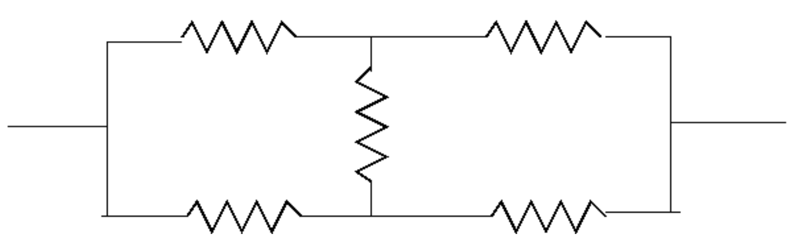

Figure DQ26.13

Q26.14 With t he switch open the bulbs are connected in series and they share the battery voltage: $\mathcal{E} = V_1 + V_2$. When the switch is closed the voltage across bulb B_2 becomes zero and no current flows through it. The voltage across B_1 becomes equal to the battery voltage and B_1 shines brighter.

Q26.15 For batteries in series the total voltage is the sum of the individual voltages. In parallel the voltage across the bulb is just the voltage of a single battery. In parallel the currents of the individual batteries add to give the total current, so more current can be delivered by batteries in parallel. Also, if one battery goes dead the others still deliver current to the device and the voltage applied to the device is unchanged.

Q26.16 With the switch open the three bulbs are connected in series and $\mathcal{E} = V_A + V_B + V_C$. When the switch is closed the voltage across bulb C becomes zero, no current flows through it and it goes out. And then $\mathcal{E} = V_A + V_B$. The voltages across A and B increase and they each shine brighter.

Q26.17 A voltmeter connected across the battery alone measured the emf. To check the internal resistance, use a voltmeter to measure the terminal voltage when the battery is connected in a circuit.

Q26.18 The time constant for an RC charging circuit is $\tau = RC_{\text{eq}}$, where C_{eq} is the equivalent capacitance, For circuit (a), $C_{\text{eq}} = C/2$. For circuit (b), $C_{\text{eq}} = 2C$. The time constant for circuit (a) is smaller and the capacitors charge at a faster rate than in circuit (b). The larger equivalent capacitance for circuit (b) means each capacitor holds more charge when fully charged so in (b) the capacitors take longer to reach their final charge.

Q26.19 The SI unit for R is Ω. $R = V/I$ so $1\,\Omega = 1\,\dfrac{\text{V}}{\text{A}}$. The SI unit for capacitance is F. $C = Q/V$ so $1\text{ F} = 1\,\dfrac{\text{C}}{\text{V}}$. $I = Q/t$ so $1\text{ C} = 1\text{ A}\cdot\text{s}$ and $1\text{ F} = 1\,\dfrac{\text{A}\cdot\text{s}}{\text{V}}$. The product RC therefore has units $\left(\dfrac{\text{V}}{\text{A}}\right)\left(\dfrac{\text{A}\cdot\text{s}}{\text{V}}\right) = \text{s}$, as was to be shown.

Q26.20 Measure the time constant τ by observing the current decay when a capacitor of known capacitance discharges through the resistor. Then $R = \tau / C$.

Q26.21 When the capacitor is fully charged the battery emf equals the voltage across the capacitor. $\mathcal{E} = Q/C$ so $Q = \mathcal{E}C$ is the maximum charge. When the charging is complete there is no current through the resistor and the resistor plays no role. The resistor affects the rate at which the capacitor charges.

CHAPTER 27
MAGNETIC FIELD AND MAGNETIC FORCES

Discussion Questions

Q27.1 There is no force when $\vec{v}$ and $\vec{B}$ are parallel, so if the charge moves along a field line there will be no force on the charge.

Q27.2 The direction of the force depends not only on the direction of the magnetic field but also on the direction of the velocity of the particle. Two particles with different velocities at the same point will have forces in different directions so this definition of the direction of $\vec{B}$ won't be unique.

Q27.3 No, your left hand will give the opposite direction for the force.

Q27.4 No. For example, if the magnetic field lines are straight lines a charged particle initially moving along a field line will experience no magnetic force and will continue moving parallel to the field lines.

Q27.5 No. If the initial velocity is perpendicular to the magnetic field the particle will travel in a semicircle but will then exit the field again.

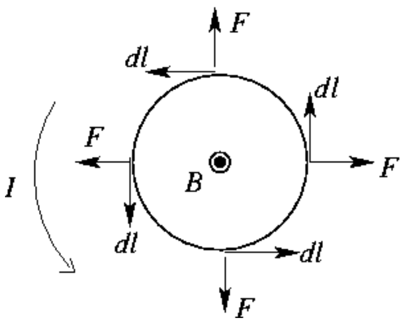
Q27.6 The magnetic force doesn't change the speed of the particle but changes the direction of the velocity. Any centrifugal force in circular motion behaves in this way, for example the tension in a string when an object attached at its end swings back and forth.

Q27.7 Yes. The net force must be zero. An electric field would produce a net unbalanced force. No. The net force must be zero so there must be no magnetic force on the particle. But there could still be a magnetic field parallel to the velocity of the particle.

Q27.8 If the current loop is pivoted about a vertical diameter, the earth's magnetic field will provide a torque that aligns the normal to the loop with the earth's field. The earth's magnetic field points toward the north geographic pole. The right-hand rule determines the direction of $\vec{B}$ of the loop, as illustrated in Fig.27.32. When $\vec{B}$ of the loop is in the direction of the earth's field the loop is in a position of stable equilibrium. The loop can determine the direction of the earth's field.

Q27.9 Find the orientation of the wire for which there is no force; the magnetic field is parallel to this direction. Then rotate the wire 90° so it is perpendicular to the field. The two possible directions of $\vec{B}$ give forces in opposite directions so observation of the direction of this force determines the direction of $\vec{B}$.

Q27.10 The magnetic field must be perpendicular to the plane of the loop. The current must travel around the loop in a direction so that the magnetic force on the current at each point is radially outward, as shown in the two sketches in Fig. DQ27.10.



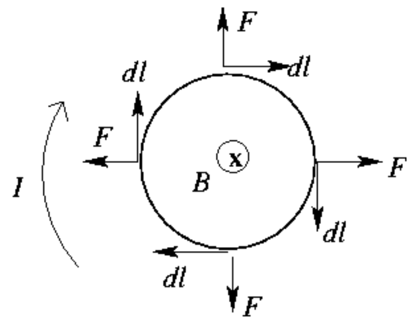


Figure DQ27.10

Q27.11 Assume the charges are moving from left to right in the plane of the page when they enter the magnetic field region. (a) A semicircular path in the counterclockwise direction, with radius $R = \dfrac{mv}{qB}$.

(b) A semicircular path in the counterclockwise direction, with radius $R = \dfrac{2mv}{qB}$.

(c) A semicircular path in the clockwise direction, with radius $R = \dfrac{mv}{|q|B}$. (d) There would be no force on the particle and it would travel in a straight line.

Q27.12 The direction of the force is given by the right-hand rule that is illustrated in Fig.27.7. If $\vec{\boldsymbol{v}}$ is parallel or antiparallel to $\vec{\boldsymbol{B}}$, then the force is zero. $\vec{\boldsymbol{B}} = B\hat{\boldsymbol{i}}$.
a: Force is in the $-z$-direction. $\vec{\boldsymbol{v}} = y\hat{\boldsymbol{j}}$. $\vec{\boldsymbol{v}} \times \vec{\boldsymbol{B}} = vB(\hat{\boldsymbol{j}} \times \hat{\boldsymbol{i}}) = vB(-\hat{\boldsymbol{k}})$.
b: Force is in $+y$-direction. $\vec{\boldsymbol{v}} = v\hat{\boldsymbol{k}}$. $\vec{\boldsymbol{v}} \times \vec{\boldsymbol{B}} = vB(\hat{\boldsymbol{k}} \times \hat{\boldsymbol{i}}) = vB\hat{\boldsymbol{j}}$.
c: Force is zero. $\vec{\boldsymbol{v}} = v(-\hat{\boldsymbol{i}})$. $\vec{\boldsymbol{v}} \times \vec{\boldsymbol{B}} = vB(-\hat{\boldsymbol{i}}) \times \hat{\boldsymbol{i}} = 0$.
d: Force is in $-y$-direction. $\vec{\boldsymbol{v}} = \dfrac{v}{\sqrt{2}}(\hat{\boldsymbol{i}} - \hat{\boldsymbol{k}})$. $\vec{\boldsymbol{v}} \times \vec{\boldsymbol{B}} = \dfrac{vB}{\sqrt{2}}(\hat{\boldsymbol{i}} - \hat{\boldsymbol{k}}) \times \hat{\boldsymbol{i}} = \dfrac{vB}{\sqrt{2}}(-\hat{\boldsymbol{j}})$.
e: The force has equal components in the $-y$ and $-z$ directions.
$\vec{\boldsymbol{v}} = \dfrac{v}{\sqrt{2}}(\hat{\boldsymbol{j}} - \hat{\boldsymbol{k}})$. $\vec{\boldsymbol{v}} \times \vec{\boldsymbol{B}} = \dfrac{vB}{\sqrt{2}}(\hat{\boldsymbol{j}} - \hat{\boldsymbol{k}}) \times \hat{\boldsymbol{i}} = \dfrac{vB}{\sqrt{2}}(-\hat{\boldsymbol{k}} - \hat{\boldsymbol{j}}) = -\dfrac{vB}{\sqrt{2}}(\hat{\boldsymbol{j}} + \hat{\boldsymbol{k}})$.

Q27.13 The maximum force per unit length of the flagpole is IB and for $I = 10^5$ A and $B = 5 \times 10^{-5}$ T (comparable to the earth's field), $F/l = 5$ N. This is not enough force to bend a metal flagpole.

Q27.14 No. The magnetic force is always perpendicular to the velocity of the particle and therefore does no work. The magnetic force can't change the kinetic energy of the particles. It can steer the particles but cannot increase their speeds.

Q27.15 There are two perpendicular motions. There is the movement of the charges in the wire of the loop, in the direction of the current. The magnetic force is perpendicular to this motion of the charges and doesn't affect the magnitude of the drift velocity associated with the current. Then there is the rotation of the loop. The edges of the loop have a tangential velocity that is in the direction of the magnetic force and there is work done for this motion. The magnetic force can change the rotational speed of the loop.

Q27.16 In Fig.27.39 if the polarity of the battery is reversed the current in the rotor will be reversed and the torque will be in the opposite direction. The motor will turn in the opposite direction. But, as discussed in Section 27.8, in many motors the magnetic field is provided by electromagnets and the current for the electromagnets is produced by the same battery that provides the current through the rotor. So, when the polarity of the battery is reversed both the current in the rotor and the magnetic field reverse direction and the torque on the rotor is in the same direction as before the battery was reversed. The motion could be reversed if separate voltage sources were used for the current in the rotor and for the current in the electromagnets and if the polarity of only one of these sources was reversed.

Q27.17 Yes, if the current is carried equally by positive and negative charges.

Q27.18 The Hall-effect voltage is $|E_z w|$, where w is the width along the z-axis of the strip. From Eq.(27.30) this gives $|E_z w| = v_{\mathrm{d}} B_y w = J_x B_y w / nq$. For semiconductors the concentration n of current carrying charges is smaller than for a metal, so the Hall voltage is larger. For the same current density the drift velocity must be larger for a semiconductor since there are fewer current-carrying charges in a given volume. The larger drift velocity results in a larger magnetic force, and this larger force produces more charge separation between the edges of the strip.

CHAPTER 28
SOURCES OF MAGNETIC FIELD

Discussion Questions

Q28.1 It would be analogous to a point charge. Magnetic field lines would terminate on it. The magnetic flux through a closed surface would be proportional to the net number of magnetic monopoles in the volume enclosed by the surface.

Q28.2 The moving charges produce their own magnetic field. The net field is then the vector sum of the field of the moving charges and the earth's field.

Q28.3 The wire can be considered infinitely long when calculating the magnetic field at points whose distance from the wire is much less than their distance from either end of the wire.

Q28.4 The energy comes from the electrical energy of the currents, which in turn comes from the emf that drives the current through the conductors. There is no contradiction. The magnetic force is perpendicular to the direction of the drift velocity of the current-carrying electrons in the conductors so doesn't affect the magnitude of the drift velocity. The motion of the wires is perpendicular to the motion of the current-carrying charges in the wires. It is the motion of the wires, in the direction of the magnetic force, that causes work to be done by this force.

Q28.5 The wires carrying currents in opposite directions produce magnetic fields that cancel because they are in opposite directions.

Q28.6 Currents in the same direction attract and currents in opposite directions repel. If all three wires carry currents in the same direction they will all three attract each other. There is no way to have all pairs with opposite currents, so it is not possible to have all three wires repel each other.

Q28.7 The force on a conductor is due to the magnetic field of the other conductor. The field of a conductor doesn't exert a force on the conductor that produces the field. The forces between conductors are due to the magnetic force between the moving charges in one conductor and the moving charges in the other conductor.

Q28.8 The two loops attract each other. The magnetic force on the inner loop is radially outward and the magnetic force on the outer loop is radially inward.

Q28.9 Adjacent turns of wire carry currents in the same direction and therefore attract each other.

Q28.10 The Biot-Savart law applies directly to an infinitesimal current element. In a practical calculation for an actual current configuration an integral must be done. The difficulty of applying the Biot-Savart law depends on the difficulty of performing that integral for the particular current configuration. When you us the Biot-Savart law you solve directly for $\vec{\boldsymbol{B}}$ at a point. Ampere's law relates a line integral around a closed path to the total current enclosed by the path. Ampere's law is easiest to apply when a path can be chosen for which $\vec{\boldsymbol{B}}$ is tangent to the path and constant at all points on the path. Ampere's law involves $\vec{\boldsymbol{B}}$ at many points simultaneously. This is an advantage for calculating B when B is the same at all these points.

Q28.11 For a toroidal solenoid the space inside the solenoid closes on itself so the field lines can stay inside the solenoid and still close on themselves. Field lines for a straight solenoid must leave the interior of the solenoid to close on themselves.

Q28.12 (a) No. Between the two wires the fields of the wires are in the same direction so they don't cancel. Above both wires or below both wires the two fields are in opposite directions, but all points in these regions are closer to one wire than to the other. Therefore, the two magnetic fields can't have the same magnitude and can't completely cancel even though they are in opposite directions. (b) Yes. Between the two wires the fields of the wires are in opposite directions. At a point midway between the two wires, the same distance from each wire, the magnitudes of the two fields are equal so they cancel completely.

Q28.13 Two parallel conductors carrying current in the same direction attract each other. So, the current in *L* must be from right to left and this requires *b* to be the positive terminal of the battery.

Q28.14 At the center of the ring $B_0 = \frac{\mu_0 I}{2a}$. On the axis of the ring at a distance *x* from the center of the ring, $B = \frac{\mu_0 I a^2}{2\left(x^2 + a\right)^{3/2}}$. If *a* is doubled, the field at the center of the ring is halved. The field at *P* changes by a different factor. For example, if *x* is much larger than *a* then $B = \frac{\mu_0 I a^2}{2x^3}$ and *B* increases by a factor of four when *a* is doubled.

Q28.15 Since $F = IlB\sin\phi$, $1\ \text{N} = 1\ \text{A}\cdot\text{m}\cdot\text{T}$. $1\ \text{N}\cdot\text{m} = 1\ \text{A}\cdot\text{m}^2\cdot\text{T}$. $1\ \text{N}\cdot\text{m} = 1\ \text{J}$ so $1\ \text{J} = 1\ \text{A}\cdot\text{m}^2\cdot\text{T}$ and $1\ \text{J/T} = 1\ \text{A}\cdot\text{m}^2$.

Q28.16 Smaller permeability means it is more difficult for an external magnetic field to align the atomic magnetic moments of the material. The tendency of the atomic magnetic moments to align themselves parallel to the magnetic field is opposed by their random thermal motion, and the energy of this motion increases with increasing temperature.

Q28.17 The magnetic susceptibility of liquid oxygen must be larger than that of liquid nitrogen. The magnet does attract oxygen gas to its poles but the force is too small to affect the random motion of the molecules associated with their temperature.

Q28.18 If each atom has a net magnetic moment then the material is paramagnetic. If the net magnetic moment of each atom is zero in the absence of an external field, but if an external field can induce a net magnetic moment, then the material is diamagnetic.

Q28.19 Paramagnetism is due to partial alignment of the magnetic moments of individual atoms and this alignment is disrupted by the random motion of the atoms, motion that increases when the temperature increases. Diamagnetic susceptibility depends on how easy it is to induce a net magnetic moment in an atom that has no magnetic moment in the absence of the external field. This effect is independent of the initial orientation of the atom so is not affected much by temperature.

Q28.20 The effect is based on conservation of angular momentum. As shown in Fig.28.24, the atomic magnetic moment is directed opposite to the atomic angular momentum. So, when the cylinder is magnetized and the atomic magnetic moments are partially aligned to produce a net magnetic moment, the atomic angular momenta are also aligned and produce a net angular momentum of the cylinder. This angular momentum is due to motion at the atomic level and not to rotation of the cylinder. But when the cylinder's magnetic moment reverses direction this net atomic angular momentum also reverses direction and by conservation of angular momentum the cylinder must rotate so its rotational angular momentum will keep the total angular momentum constant.

CHAPTER 29
ELECTROMAGNETIC INDUCTION

Discussion Questions

Q29.1 Pulling the sheet from between the poles changes the magnetic flux through the sheet and this causes induced currents in that sheet. By Lenz's law, the force of the field on these induced currents opposes the motion of the sheet. The induced current and hence the force is greater when the flux changes more rapidly, when the sheet moves with greater speed. The same thing happens when the sheet is inserted. In each case the force exerted on the induced currents by the magnetic field is directed to oppose the motion of the sheet.

Q29.2 The induced current changes direction after every half-revolution of the loop. When the angular speed is doubled the rate of change of the flux doubles and this causes the induced emf and induced current to double. The torque required is proportional to the current in the loop, so the torque also doubles.

Q29.3 The loops are sketched in Fig. DQ29.3. In the sketch let loop 1 be the one with the varying current I and let loop 2 be the closed ring in which current is induced. Let the current in loop 1 be counterclockwise. The flux through loop 2 due to the current in loop 1 is directed into the plane. When I increases, the increasing flux into the plane inside loop 2 induces a clockwise current. When I decreases, the decreasing flux into the plane inside the loop 2 induces a counterclockwise current. When the current in the first loop is increasing the two currents are in opposite directions. When the current in the first loop is decreasing the two currents are in the same direction.

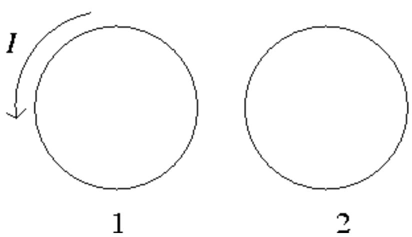

Figure DQ29.3

Q29.4 The SI units of the quantity BvL are $\text{T}\cdot\text{m}^2/\text{s}$. Since $\Phi_B = BA\cos\phi$, $1\ \text{Wb} = 1\ \text{T}\cdot\text{m}^2$. $\mathcal{E} = -\dfrac{d\Phi_B}{dt}$ so $1\ \text{V} = 1\ \text{Wb/s}$ and $1\ \text{Wb} = 1\ \text{V}\cdot\text{s}$. Therefore, $1\ \text{V}\cdot\text{s} = 1\ \text{T}\cdot\text{m}^2$ and $1\ \text{T} = 1\ \dfrac{\text{V}\cdot\text{s}}{\text{m}^2}$.
Then $1\ \text{T}\cdot\text{m}^2/\text{s} = \left(1\ \dfrac{\text{V}\cdot\text{s}}{\text{m}^2}\right)\left(1\ \dfrac{\text{m}^2}{\text{s}}\right) = 1\ \text{V}$, as was to be shown.

Q29.5 No. The magnetic field of the conductor is parallel to the ring and produces no flux through it. So, there is no induced emf when the current changes.

Q29.6 The moving magnet induces currents in the pipe and there is a force exerted between these currents and the magnet. By Lenz's law the force on the magnet is directed to oppose its motion, so this force is upward. The induced current and hence the force on the magnet increases as the speed of the magnet increases. The terminal speed is reached when this upward force equals the weight of the magnet.

Q29.7 See Fig. DQ29.7. $\vec{v}\times\vec{B}$ is to the right, so positive charge collects toward the right; the right-hand wing tip is at higher potential. The answer does not depend on the direction the plane is flying.

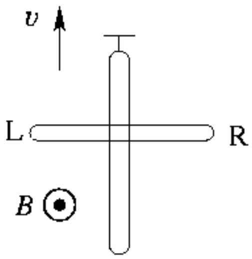

Figure DQ29.7

Q29.8 Just after the switch is closed the current increases from zero to a nonzero value in the counterclockwise direction. The magnetic field of the current in the larger loop us out of the page at the location of the small loop. Since the flux is increasing the induced current in the small loop is clockwise. The currents in the two loops therefore are in opposite directions and the two loops repel. The large loop exerts a force on the small loop that is radially inward at each point around the loop. This is consistent with Lenz's law: the induced current is directed so as to oppose the increase in flux by exerting a force that is directed to reduce the area of the small loop.

Q29.9 Let the wire and loop be positioned as in Fig.E29.7 and let the current in the wire be in the direction shown in that figure. The magnetic field is into the page at the location of the rectangle. Since the current I in the wire is decreasing the flux through the rectangle is decreasing and the induced current in the rectangle is clockwise. For the side of the rectangle closest to the wire the currents in the wire and rectangle are in the same direction and the force the wires exert on each other is attractive. For the side of the rectangle farthest from the wire the two currents are in opposite directions and the force is repulsive. But the attractive force is stronger than the repulsive force, since the force is inversely proportional to the distance between the wires. So, the net force on the rectangle is attractive, toward the wire. This is consistent with Lenz's law: the induced current is directed so as to pull the loop closer to the wire. This opposes the decrease in flux by pulling the rectangle closer to the wire, where the magnetic field is stronger.

Q29.10 If the axis of rotation is parallel to the magnetic field there is no magnetic flux through the loop at any position during its rotation so there is no change in flux and no induced emf.

Q29.11 For the slidewire to move at constant speed the net force on it must be zero. The external force F_{net} must equal the magnetic force F that acts on the slidewire due to the induced current. So, $F_{\text{ext}} = B^2L^2v^2 / R$. If there is a break in the circuit there is no induced current and in the absence of friction no external force is required for motion with constant speed.

Q29.12 No. The work done on an electron by the induced electric field during a complete trip around the loop is $e\mathcal{E}$. The same amount of energy is removed from the electron due to the resistance R of the loop. No. The induced electric field is a nonconservative field and is not associated with a potential difference.

Q29.13 (a) $\Phi_B = BA$. $|\mathcal{E}| = \left|\dfrac{d\Phi_B}{dt}\right| = A\left|\dfrac{dB}{dt}\right| = \pi r^2\left|\dfrac{dB}{dt}\right|$, where r is the radius of the ring. If r is doubled, then $|\mathcal{E}|$ is increased by a factor of 4. (b) $\int \vec{E}\bullet d\vec{l} = -\dfrac{d\Phi_B}{dt}$ gives $E(2\pi r) = \pi r^2\left|\dfrac{dB}{dt}\right|$ and $E = \frac{1}{2}r\left|\dfrac{dB}{dt}\right|$. Doubling r doubles E, the electric field induced in the ring.

Q29.14 As the magnet on the flywheel moves past the stationary coil the magnetic flux through the coil changes and a current is induced in the coil.

Q29.15 No, this is not what Lenz's law says. Lenz's law says that the induced current in a metal loop always flows to oppose the *change* in the magnetic flux through the loop.

Q29.16 No. The induced emf doesn't depend on the size of the magnetic flux. It instead depends on the rate of change of the flux.

Q29.17 Yes, a time-varying current corresponds to a time-varying electric field and a displacement current.

Q29.18 Yes. The dielectric is an insulator and there is no conduction current in the dielectric. These equations apply to the situation shown in Fig. 29.22. The equations show that the conduction current in the wires carrying charge to and from the capacitor plates equals the displacement current in the space between the plates.

Q29.19 (a) Eq.(29.20); (b) Eq.(29.21); (c) Eq.(29.18); (d) Eq.(29.19).

Q29.20 The electric field lines would have the same shape as the magnetic field lines produced by an electric current in a wire: concentric circles perpendicular to the wire, with the wire passing through the center of the circles.

Q29.21 Zero. Unless some of the regions of resistance completely fill a cross-sectional area of the cylinder, the super conducting regions provide a zero-resistance path for the current.

CHAPTER 30
INDUCTANCE

Discussion Questions

Q30.1 When the contact is broken the current abruptly decreases and there is a large induced current in the attachment.

Q30.2 $\mathcal{E} = -\dfrac{d\Phi_B}{dt}$ says $1\ \text{Wb} = 1\ \text{V}\cdot\text{s}$. $I = \dfrac{V}{R}$ says $1\ \text{A} = 1\ \text{V}/\Omega$.

Therefore, $1\ \text{Wb/A} = (1\ \text{V}\cdot\text{s})\left(1\ \dfrac{\Omega}{\text{V}}\right) = 1\ \Omega\cdot\text{s}$, as was to be shown.

Q30.3 Mutual inductance is a measure of how much flux through coil 2 is produced by a given current in coil 1. If coil 2 is rotated 90° the flux through it is greatly reduced, so the mutual inductance decreases.

Q30.4 The field is confined to the space enclosed by the windings. And if the difference between the inner and outer radii of the toroid is small compared to the inner radius, the variation of the field across the cross section of the windings is small. This makes it easy to calculate the flux through one turn of the coil.

Q30.5 series: If the current passes through each coil in the same sense, then the two in series are equivalent to one coil with twice the length and twice the number of turns. Exercise 30.15 shows that the self-inductance L for a long, straight solenoid with N turns, cross-sectional area A and length l is $L = \mu_0 N^2 A / l$. Doubling N and l causes L to increase by a factor of two. The number of turns per unit length is the same as for a single coil so the flux Φ_B through one turn is the same, but there are twice the number of turns and $L_{\text{series}} = 2L$.

parallel: The emf across the combination is the emf across each coil. Each coil gets half the current so the magnetic field in each coil is half what it would be with only a single coil in the same circuit. Hence the flux through one coil is halved, the induced emf in each coil is halved, and the inductance of the combination is $L/2$; $L_{\text{parallel}} = L/2$.

To get $L = 0$ connect the two coils in series such that the current passes around one in the opposite sense than for the other. The induced emfs in the coils are in opposite directions and cancel.

Q30.6 The area is $A = \pi r^2$. The magnetic field at the center of N circular loops of radius r is $\mu_0 NI / 2r$. The flux is then proportional to r. $L = N\Phi_B / i$ so the coil with twice the radius has twice the self-inductance.

Q30.7 Yes, this would work. The induced emfs for each half of the windings would be in opposite directions and would cancel. There would be no net induced emf and L would be zero.

Q30.8 $u = B^2 / 2\mu$ so for the same magnetic field the energy density is larger in a vacuum, since $\mu > \mu_0$. For a long solenoid the field inside the solenoid is given by $B = \mu n I$. $u = B^2 / 2\mu$ then gives $u = \mu n^2 I^2 / 2$. The energy density for constant I is proportional to μ and for the same current more energy is stored when the solenoid is filled with a ferromagnetic material, that has $\mu >> \mu_0$.

Q30.9 The voltage across the resistor is proportional to the current through it, the voltage across the inductor depends on the rate of change of the current and the voltage across the capacitor depends on the charge on its plates. (a) In the *R*-*C* circuit, just after the switch is closed the charge on the capacitor is zero and the full battery voltage appears across the resistor. In the *R-L* circuit, just after the switch is closed the current is still zero but is increasing at its maximum rate. The full battery voltage is across the inductor. (b) In the *R-C* circuit, the full battery voltage is across the capacitor and the current is zero. In the *R-L* circuit, the current is no longer changing, the full battery voltage is across the resistor and the current is a maximum. The capacitor has no effect initially but causes the current to go to zero as time progresses. The inductor initially limits the rate at which the current can increase but after a long time it has no effect on the circuit.

Q30.10 (a) The voltage across the inductor is proportional to the rate of change of the current flowing in the inductor. The pattern on the oscilloscope is shown in Fig. DQ30.10. (b) Since the voltage across the inductor is determined by the direction of the current, the V versus t graph is indeed proportional to the derivative of the current graph.

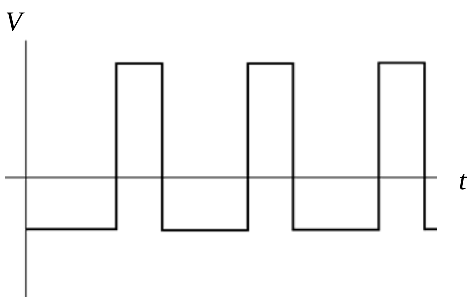

Figure DQ30.10

Q30.11 The current is now flowing in the negative direction. The current is increasing in magnitude so is becoming more negative, and this means $di/dt < 0$.

Q30.12 A decrease in charge on the capacitor corresponds to i flowing in the negative direction and $i = dq/dt$ correctly says this.

Q30.13 The potential v_{ac} must satisfy Kirchhoff's loop rule. So when other potentials around the loop change abruptly, such as abruptly adding $\mathcal{E}$ to the loop, v_{ac} must change abruptly. But $v_{bc} = L\,di/dt$. v_{bc} must equal $\mathcal{E} - iR$ and can't be larger than $\mathcal{E}$. Since v_{bc} is limited, di/dt is also limited.

Q30.14 The inductor and resistor are in series; all current through R must also pass through L.

Q30.15 The voltage induced across the inductor is $v_L = L|di/dt|$. If $|di/dt|$ is large then v_L is large. The large emf in the inductor produces a large current in the circuit. $v_L \to \infty$ when $|di/dt| \to \infty$ so it is not possible to stop the current instantaneously.

Q30.16 If the circuit is underdamped the current and charge oscillate, but with amplitudes that decrease each cycle of the oscillation. So the energy stored in a cycle would be less than the energy dissipated in that cycle. For an overdamped circuit there are no longer any current oscillations.

CHAPTER 31
ALTERNATING CURRENT

Discussion Questions

Q31.1 At the higher voltage, the same power can be transmitted at lower current so there is less I^2R power loss in the transmission wires. The higher voltage is more of a safety risk.

Q31.2 The polarity of the source voltages reverses when the current direction reverses. Current always enters the $-$ terminal and exits the + terminal as it passes through the source. The moving charge always gains electrical energy as it moves back and forth in the source. At a resistive load the moving charges in the current always lose electrical energy as they pass through the load in either direction. The oscillating charge at the source causes oscillating charge at the load. Electrical energy is put into the circuit at the source and consumed at the load.

Q31.3 In the inductor or capacitor electrical energy is stored and then released back to the circuit. In the resistor electrical energy is dissipated by transformation to thermal energy and not returned to the circuit.

Q31.4 When the charge on the left plate is positive but decreasing in time $|q|$ is decreasing so dq/dt is negative. The current is clockwise so is negative and $i = dq/dt$ is correct. When the charge on the right plate is positive and increasing, $|q|$ is increasing. But q refers to the charge on the left plate so is negative. A negative q that is getting larger in magnitude corresponds to $dq/dt < 0$. i is clockwise so is negative and $i = dq/dt$ is correct. When the charge on the right plate is positive and decreasing, $dq/dt > 0$ since q is negative and decreasing in magnitude. i is counterclockwise so is positive and $i = dq/dt$ is correct.

Q31.5 A resistor would dissipate electrical energy but no electrical energy is dissipated in the inductor. Electrical energy is temporarily stored in the magnetic field of the inductor but at a later time all this energy is returned to the circuit.

Q31.6 current to right through L and increasing: i is in the positive direction and increasing in magnitude so $di/dt > 0$. By Lenz's law the induced emf in the inductor is directed to oppose the increase in the current. The induced emf is therefore to the left in Fig.31.8a and this corresponds to $v_a > v_b$.

current to the right through L and decreasing: i is in the positive direction and is decreasing in magnitude so $di/dt < 0$. By Lenz's law the induced emf in the inductor is directed to oppose the decrease in the current. The induced emf is therefore to the right and this corresponds to $v_a < v_b$. v_{ab} is negative and di/dt is negative so $v_{ab} = L(di/dt)$ is still correct.

current to the left through L and increasing: i is in the negative direction and is increasing in magnitude so $di/dt < 0$. By Lenz's law the induced emf in the inductor is directed to oppose the increase in the current. The induced emf is therefore to the right and this corresponds to $v_a < v_b$. v_{ab} is negative and di/dt is negative so $v_{ab} = L(di/dt)$ is still correct.

current to the left through L and decreasing: i is in the negative direction and is decreasing in magnitude so $di/dt > 0$. By Lenz's law the induced emf in the inductor is directed to oppose the decrease in the current. The induced emf is therefore to the left and this corresponds to $v_a > v_b$. v_{ab} is positive and di/dt is positive so $v_{ab} = L(di/dt)$ is still correct.

Q31.7 No. The power factor is $\cos\phi$, where $\tan\phi = \dfrac{\omega L - 1/\omega C}{R}$. Mathematically, $\cos\phi = 0$ only if

$\phi = 90^{\circ}$. $\phi = 90^{\circ}$ gives $\tan\phi \to \infty$. This happens if $R \to 0$. This is consistent with the equation $P_{\text{av}} = \frac{1}{2}VI\cos\phi$ for the average power input to the circuit. As long as $R \neq 0$ there is some electrical power consumed in the resistor and the power factor isn't zero.

Q31.8 At any instant in time $v = v_R + v_L + v_C$. v_L and v_C are 180° out of phase so have opposite sign. v_R and $(v_L + v_C)$ are 90° out of phase and $v^2 = v_R^2 + (v_L + v_C)^2$. $|v_R|$ and $|v_L + v_C|$ must each be less than the magnitude $|v|$ of the source voltage. But since $|v_L + v_C| = ||v_L| - |v_C||$, $|v_L|$ and $|v_C|$ can each be larger than $|v|$.

Q31.9 When the circuit is far from resonance X_L and X_C differ. So if $R << X_L$ and $R << X_C$, then it will also be true that $R << |X_L - X_C|$. $|\tan\phi| = |X_L - X_C|/R$, so $|\tan\phi|$ is large and ϕ is close to $+90^{\circ}$ or -90°. The power factor $\cos\phi$ is close to zero. The current and source voltage are close to 90° out of phase and little power is delivered by the source. Since R is small, little power is consumed in the resistor and this agrees with little power delivered by the source.

Q31.10 See Q31.8. The voltages across the inductor and capacitor are 180° out of phase, so at all times have opposite polarity and subtract from each other when the loop rule is applied. The net voltage at any time across the capacitor and inductor combination can't exceed 120 V, but the capacitor voltage can be much larger than this.

Q31.11 The inductor doesn't affect R but it does increase the impedance Z of the circuit. I_{rms} and therefore $P = I_{\text{rms}}^2 R$ decrease.

Q31.12 $X_C = 1/(\omega C)$. Inserting the dielectric increases C and therefore decreases X_C. This in turn decreases Z. The rms current in the circuit increases and the bulb becomes brighter when the dielectric is inserted.

Q31.13 Inserting the iron rod increases the inductance L. $X_L = \omega L$ so X_L increases and Z increases. This in turn decreases the rms current in the circuit and the bulb becomes less bright.

Q31.14 The impedance is $Z = \sqrt{R^2 + (X_L - X_C)^2}$. An increase in Z decreases I_{rms} and the bulb becomes less bright. A decrease in Z increases I_{rms} and the bulb becomes brighter. Whether X_C^2 or $(X_L - X_C)^2$ is smaller depends on the numerical values of X_L and X_C. Similarly, whether X_L^2 or $(X_L - X_C)^2$ is smaller depends on the values of X_L and X_C. The change in brightness, whether it increases or decreases, depends on the values of X_L and X_C, and these in turn depend on L, C and the frequency f of the source.

Q31.15 Yes, this happens at the resonance frequency. At resonance $X_L = X_C$ and $Z = R$ with the capacitor and inductor present and $Z = R$ also when both are removed.

Q31.16 No. The transformer works using the induced emf that results in an ac circuit. If a transformer is connected to a dc line there is no current or voltage in the secondary.

Q31.17 (a) $V_2 = \left(\dfrac{N_2}{N_1}\right)V_1$. If N_2 is doubled, then V_2, the voltage amplitude in the secondary, doubles. (b) The effective resistance of the secondary is given by $R_{\text{eff}} = \frac{R}{\left(N_2 / N_1\right)^2}$. If N_2 is doubled the effective resistance is multiplied by a factor of $\frac{1}{4}$ and therefore decreases.

Q31.18 (a) The resonance angular frequency is given by $\omega_0 = \frac{1}{\sqrt{LC}}$. If L and C are both doubled the resonance is halved. (b) The inductive reactance is $X_L = \omega L$. If L is doubled then X_L increases by a factor of two. (c) The capacitive reactance is $X_C = \frac{1}{\omega C}$. Doubling C means X_C is halved. (d) The impedance is $Z = \sqrt{R^2 + (X_L - X_C)^2}$. Since R and X_L are doubled but X_C is halved, Z does not change by a simple factor of two.

Q31.19 The resonance angular frequency is $\omega_0 = \frac{1}{\sqrt{LC}}$. It is independent of R. To double ω_0, decrease L and C by multiplying each of them by $\frac{1}{2}$.

CHAPTER 32
ELECTROMAGNETIC WAVES

Discussion Questions

Q32.1 Yes. The direction of the vector product $\vec{\boldsymbol{E}} \times \vec{\boldsymbol{B}}$ can be determined and the wave is traveling in this direction so must have come from the opposite direction.

Q32.2 The steel girders are conductors and absorb radio waves and prevent the waves from getting to the car.

Q32.3 Visible light from a light bulb, microwaves in a microwave oven, and radio waves received by a radio are all electromagnetic waves. These waves all consist of oscillating electric and magnetic fields and travel in air with the same speed c. These different kinds of electromagnetic waves have different frequencies and therefore different wavelengths.

Q32.4 The electric fields of the intense radio waves produce currents in the signs.

Q32.5 Only transverse waves can be polarized. All electromagnetic waves can be polarized but sound waves cannot.

Q32.6 Once the wavefront reaches the charge the uniform, constant electric field in the wave will exert a constant force on the charge in the direction of $\vec{\boldsymbol{E}}$, and this gives the charge a constant acceleration.

Q32.7 The intensity of such a wave would be $I = \frac{1}{2}\epsilon_0 c E_{\max}^2 = 0.3\ \text{W/cm}^2$. This is too little energy to induce any appreciable currents in the person's body. Also, the frequency of the visible light waves is about 10^{15} Hz and it is difficult to produce such very high frequency currents in a person's body.

Q32.8 $I = \dfrac{E_{\max} B_{\max}}{2\mu_0}$. $E_{\max} = cB_{\max}$ so $I = \dfrac{c}{2\mu_0} B_{\max}^2$. For I to double, the magnetic field amplitude $B_{\max}$ is increased by a factor of $\sqrt{2}$.

Q32.9 No, the frequency of oscillation of the magnetic field of the light is about 10^{15} Hz and due to the mass of the compass needle it would take a very large current to cause it to oscillate at this extremely high frequency. The earth's field is much weaker but is constant in time.

Q32.10 The electric field of the radio waves must be polarized in the vertical direction.

Q32.11 Yes, the same momentum conservation principle applies and there is a recoil effect. But the momentum carried by the light is very small so the recoil force is also very small and is not detectable.

Q32.12 For a perfectly reflecting surface $p_{\text{rad}} = \dfrac{I}{c}$. Eq.(15.26) applies to electromagnetic waves: $\dfrac{I_1}{I_2} = \dfrac{r_2^2}{r_1^2}$. $I_2 = I_1 \left(\dfrac{r_1}{r_2}\right)^2$. If the distance is doubled then the intensity is multiplies by $\dfrac{1}{4}$ and the radiation pressure p_{rad} is multiplied by $\dfrac{1}{4}$. Therefore, the radiation pressure would be $p/4$.

Q32.13 The standing wave has energy in its electric and magnetic fields but does not transport energy through space like a traveling wave does. Similarly, the electric and magnetic fields in the standing wave have momentum but there is no momentum flow like there is for a traveling wave. As shown in Example 32.6 the intensity or time average of $\vec{S}$ at any point in a standing wave is zero.

CHAPTER 33
THE NATURE AND PROPAGATION OF LIGHT

Discussion Questions

Q33.1 Light travels only very slightly slower in air than in vacuum. And the distance it travels in the earth's atmosphere is a very small fraction of the total distance. The delay due to the earth's atmosphere is very, very small.

Q33.2 Light travels slower in the atmosphere than in vacuum; the refractive index of air is slightly greater than unity. When light goes from one material to another of larger refractive index it is bent toward the normal. The normal to the earth's atmosphere is vertical. This bending of starlight as it enters the atmosphere does mean that stars are not precisely where they appear to be.

Q33.3 The frequency f of the wave doesn't change when passing from one material to another. Since the interface cannot create or destroy waves, the number of wave cycles arriving per unit time must equal the number leaving per unit time. The period T is $T = 1/f$ so T also doesn't change. The wavelength decreases when the speed of light decreases. The distance traveled during one period is less when the wave speed is less, so the wavelength, the distance occupied by one cycle, decreases.

Q33.4 The sun can be seen even though it is below the horizon; see Problem 33.51. Similarly, the sun can be seen before it rises. This does slightly increase the time between the apparent sunrise and the apparent sunset.

Q33.5 The refractive index of air depends on the temperature of the air. Light passing through the moving warm air produces this effect.

Q33.6 $v = \dfrac{c}{n}$ so measuring n is equivalent to measuring v. (a) Let a ray of light in air refract into the glass and measure θ_a and θ_b, where a is air and b is glass. For air $n = 1.00$ and Snell's law, $n_a \sin\theta_a = n_b \sin\theta_b$, allows n_b to be calculated. (b) For light traveling in the glass measure the critical angle for a glass-air interface. $\sin\theta_{\text{crit}} = \dfrac{1.00}{n_{\text{glass}}}$ and n_{glass} can be calculated. (c) Reflect light traveling in air from the surface of the glass. Use a polarizing filter to measure the polarizing angle θ_{p}, the incident angle at which the reflected light is completely polarized perpendicular to the plane of incidence. Then the equation $\tan\theta_{\text{p}} = \dfrac{n_b}{n_a}$, where a is air and b is glass, can be used to calculate the refractive index of the glass.

Q33.7 One image is caused by reflection at the front surface of the window glass and the other from reflection at the back surface.

Q33.8 Light travels from the fish to the surface of the water, reflects there and travels to your eyes. The surface of the water, at the interface between the water and the air, forms an image of the fish, just like a conventional flat mirror. Each point in the image is the same distance above the surface of the water as the corresponding point on the fish is below the surface (see chapter 34), so the image is upside down. The top of the fish is on the bottom of the image.

Q33.9 No. Total internal reflection occurs only when light is incident in the material of larger refractive index. The refractive index of air is less than that of glass.

Q33.10 The angle of reflection equals the angle of incidence in all materials and for all wavelengths.

The angle of refraction depends on the indices of refraction of the two materials and the index of refraction depends on wavelength.

Q33.11 Take two pair and rotate one pair in relation to the other, as in Fig.33.25. If the transmitted intensity depends on the angle the one pair is rotated, then the lenses are Polaroid filters.

Q33.12 No. Only transverse waves exhibit polarization.

Q33.13 Produce polarized light, polarized along the horizontal direction, by letting the light reflect from the horizontal surface of water with the incident angle equal to the polarizing angle. Hold the filter vertical and rotate it until the intensity of this light transmitted through the filter is a maximum. In this position the polarizing axis of the polarizer is horizontal.

Q33.14 Yes, it would work. The light reflected from the roadway is partially polarized parallel to roadway. The polarizing axis of the windshield would need to be vertical to block this polarized component of the reflected light. An advantage is that it would be built into the car. A disadvantage would be that it would reduce the transmitted light that comes directly from the objects. All objects would appear dimmer.

Q33.15 The plastic wrap becomes birefringent when stretched and alters the polarization of the light passing through it.

Q33.16 The reflected light, the glare, is partially polarized in a horizontal direction. The polarizing axis of the Polaroid sunglasses is vertical, so this axis is perpendicular to the polarization axis of the glare and the sunglasses don't pass this light when your head is upright. But when you lie on your side the polarizing axis is horizontal and the glasses pass the reflected light.

Q33.17 Yes, it is true. The axis of the third polarizer has a nonzero component in both perpendicular directions. The third polarizer rotates the polarization axis of the light that has passed through the first polarizer.

Q33.18 The electromagnetic waves carrying the TV signal are polarized in a horizontal direction perpendicular to the direction of propagation of the wave. Therefore, the plane of the "ears" should be perpendicular to the direction from your location to the location of the transmitter for the TV station, so that the antenna will align with the electric field of the TV signal.

Q33.19 Light is scattered in all directions in the yz-plane so removes all polarization components equally from the incident light and the transmitted light is still unpolarized. Only scattering in the $-y$-direction is shown in Fig.33.31 since that is where our sunbather is.

Q33.20 Fig.33.31 shows that when the sun is low in the western sky the light scattered downward to the surface of the earth is polarized in a north-south direction. The polarizing axis of the Polaroid sunglasses is along the line that runs from your mouth to nose to between your eyes. You want this axis to be perpendicular to the north-south polarization direction of the light, so lie along an east-west line. It doesn't matter if your feet point west or east.

Q33.21 Light scattered from blue sky is scattered from linear molecules in the atmosphere that have a linear axis. Light scattered from cloud is not scattered by individual molecules but instead from water droplets or ice crystals that have no axis.

Q33.22 The scattered light contains much more blue light than red. The red-tinted sunglasses filter out the blue scattered light and pass the red light, which is predominantly light that hasn't been scattered by the particles or droplets.

Q33.23 Sunrises are red when the air is dusty or smoky. Human activities and wind during the day add dust and pollutants to the air during the day. Much of this material settles out during the night as so the air is cleaner at sunrise than at sunset.

Q33.24 In Fig.33.36, light travels slower in the air near the hot surface of the earth. For sound at night, sound travels slower in the cool air nearer the surface and follows a curved path just like that shown in Fig.33.36.

Q33.25 Yes, water waves can be reflected and refracted. Water waves produced by dropping a rock in a pool of water reflect from a surface that is perpendicular to the water. Water waves depend on the depth of the water so the waves refract at a line where the depth changes. Huygen's principle applies to all wave phenomena.

CHAPTER 34
GEOMETRIC OPTICS

Discussion Questions

Q34.1 Each section of a spherical mirror forms the entire image. The image formed by the bottom half of the mirror will be formed at the same location as the image formed by the mirror before it was cut in half. The only difference is that the image will be less intense (dimmer) because half as much light is reflected by half the mirror.

Q34.2 The image is on the side of the interface where the light comes from so the image is virtual and s' is negative.

Q34.3 The concave surface acts as a converging mirror for the waves and focuses the light to form the desired real image at the receiver. The image of the very distant object is at the focal point of the surface. The receiver should be a distance $f = R/2$ from the vertex of the surface.

Q34.4 $f = R/2$. For a flat surface $R \to \infty$ so $f \to \infty$. For a very distant object the image is very far from the mirror, corresponding to a focal point very far from the mirror. Rays incident parallel to the normal to the mirror are reflected parallel to the normal.

Q34.5 The focal length of the mirror follows from the curvature of the mirror and the laws of reflection. The law of reflection is independent of the wavelength of the light and the focal length doesn't change when the mirror is immersed in water.

Q34.6 $s' = sf/(s-f)$. For a real image $s' > 0$. For real objects, concave mirrors ($f > 0$) form real images when $s > f$. For real objects, convex mirrors ($f < 0$) never form real images.

Q34.7 Each image formed by one mirror serves as the object for the other mirror. At each reflection not all the light is reflected, so the more reflections to form an image the dimmer that image.

Q34.8 For $s = f$, a point object at the focal point of the mirror, the reflected rays are parallel to the mirror axis and no image is formed. The rays neither converge to a real image nor appear to diverge from a virtual image behind the mirror. For $s > f$, as s approaches f the real image becomes farther and farther from the mirror and becomes larger and larger. The image is large but it is also far away; its angular size is the same as the angular size relative to the mirror of the object. For $s < f$, as s approaches f the virtual image becomes farther and farther from the mirror and becomes larger and larger.

Q34.9 The mirror forms a virtual image that is smaller than the object. The purpose of the mirror is to allow you to see a wide area behind you, for safety. A concave mirror could also form a reduced image, for object distances greater than twice the focal of the mirror. But such images are real and therefore inverted, which is not desirable. The focal length is determined so that the desired viewing area has an image size that fits on the mirror surface.

Q34.10 Yes, a real image of the sun is formed at the focal point of the concave mirror. Rays are focused here and the image is bright. A convex mirror diverges the rays and doesn't focus them at a point; it doesn't work with a convex mirror.

Q34.11 If his face's distance s from the vertex of the surface is greater than $R/2$, where R is the radius of curvature of the spoon, the person sees a real, inverted image. For $s < R/2$ the image is upright. The convex side forms virtual, upright images no matter how far his face is from the spoon.

Q34.12 For s exactly equal to f the reflected rays are parallel to the axis and there is no image formed. For $s > f$, as s approaches f the real image gets larger and larger and farther and farther from the mirror. s' is positive and gets larger and larger as $s \to f$. For $s < f$, as s approaches f the virtual image gets larger and larger and farther and farther from the mirror. s' is negative and its magnitude gets larger and larger as $s \to f$.

Q34.13 $m = +1$ is a statement about the lateral magnification. $m = +1$ says that the object PQ has the same length as the image $P'Q'$, and this is what Fig.34.26 shows. The difference in length of the vertical arrow and its image refers to the longitudinal magnification. The longitudinal magnification for refraction at a plane refracting surface is not $m = +1$.

Q34.14 Yes. The mirror forms a reduced image so the car appears to be farther away than its actual distance.

Q34.15 Take a piece of paper and move the paper until the image of a distant object, such as the sun is focused on the paper. Then the distance between the lens and the paper is the focal length of the lens. The virtual image formed by a diverging lens cannot be focused onto a piece of paper, so this method cannot be used for a diverging lens.

Q34.16 The focal length of a thin lens is given by Eq.(34.19). The refractive index n of the lens material depends on the wavelength of the light and this causes f to depend on the wavelength. But the factor $n-1$ is always greater than zero so f has the same sign for all wavelengths.

Q34.17 When the lens is in water rather than in air the refractive indices of the lens and surrounding material are closer in value than when the lens is in air. Therefore, light is bent less when it enters and exits the lens and the focal length is greater when the lens is in water. (See Problem 34.92.)

Q34.18 A spherical drop of water acts as a converging lens and $|f|$ is proportional to the radius of curvature of the drop; a small radius gives a small focal length. For an air bubble the role of the two refractive indices, air and water, are reversed and the air bubble acts as a diverging lens. The magnitude of its focal length increases when its radius increases. A detailed analysis can be carried out by treating refraction as light enters and leaves the bubble. The bubble cannot be treated as a thin lens because the distance between the two surfaces where refraction occurs is not small compared to the radius of these surfaces.

Q34.19 Yes. This is discussed in the textbook at the end of Section 34.1 and this principle is used in Section 34.4 in the derivation of the lensmaker's equation. It doesn't matter if the first image is real or virtual. The concept of a first image is a convenient way to describe the direction the rays are traveling, either from or toward a real image or appearing to come from a virtual image, when they reach the second surface.

Q34.20 The rays of light do not converge at a virtual image but instead seem to come from a virtual image, so a virtual image cannot be projected onto film. But a virtual image can be photographed with a camera, just as an object or real image can be photographed by letting light from the object or image enter the camera lens. A simple example is a photograph of an image in a plane mirror.

Q34.21 All the formulas are the same if the image and object are interchanged. n_a and n_b must be interchanged and also y and y' in $m = y'/y$. Reversibility requires that the formulas be unchanged by the interchange of image and object.

Q34.22 A simple refracting telescope uses two converging lenses. The lens for the eyepiece should have a large focal length and the lens for the eyepiece needs to have a short focal length. Converging lenses will focus sunlight to a sharp point on the ground and a diverging lens won't. The distance from the lens to the ground when the sunlight is sharply focused on the ground is the focal length of the lens.

Q34.23 Water on one side of the eye affects the refracting property of the eye. An image focused on the retina when air is on the outside of the eye is not focused when the air is replaced by water. Yes, you could wear eyeglasses that correct your underwater vision. The water has a refractive index closer to that of the eye so reduces the bending of the light as it enters the eye. To compensate for this you should use converging lenses in the eyeglasses.

Q34.24 Each section of a lens forms the entire image. The image formed by the bottom half of the lens will be identical in location, size and orientation to the image formed by the full lens. The only difference is that the image will be less intense (dimmer) because half as much light passes through the masked lens.

CHAPTER 35
INTERFERENCE

Discussion Questions

Q35.1 Being in water reduces the wavelength. This causes the interference maxima to be more closely spaced (Eq.35.6).

Q35.2 Longitudinal waves obey the principle of superposition and interfere so a two-source interference experiment can be done with sound waves. The sources must be coherent, such as two loudspeakers driven by the same amplifier. The wavelength for sound waves is much larger than for visible light so if $d \approx \lambda$ then the two sources would be farther apart in the sound experiment. Reflection of the sound waves would need to be suppressed.

Q35.3 When θ is small, $y_m = R\frac{m\lambda}{d}$ and the distance on the screen between adjacent bright fringes is $\Delta y = y_{m+1} - y_m = \frac{R\lambda}{d}$. Δy doesn't depend on *m*, so adjacent fringes are equally spaced near the center of the screen, where θ is small. For any angle, $y_m = R\tan\theta_m$ and $\sin\theta_m = \frac{m\lambda}{d}$. $y_m = R\frac{m\lambda}{d}$ is derived by setting $\sin\theta_m \approx \tan\theta_m$, valid for small θ_m. For larger angles, $\tan\theta_m$ is increasingly larger than $\sin\theta_m$ and adjacent fringes get farther and farther apart as the distance from the center of the screen increases.

Q35.4 For small angles, bright fringes are located by $y_m(\text{bright}) = R\frac{m\lambda}{d}$ and the distance between adjacent bright fringes is $\Delta y(\text{bright}) = y_{m+1} - y_m = \frac{R\lambda}{d}$. For small angles, dark fringes are located by $y_m(\text{dark}) = R\frac{(m+\frac{1}{2})\lambda}{d}$. The distance on the screen between a bright fringe and an adjacent dark fringe is $y_m(\text{dark}) - y_m(\text{bright}) = \frac{R\lambda}{2d}$. Near the center of the screen, where the small angle approximation is valid, the bright fringes are midway between the dark fringes. This is no longer true away from the center of the screen, where the small angle approximation is no longer valid. Then a bright fringe is not midway between dark fringes but instead is somewhat closer to the adjacent dark fringe of smaller *m*.

Q35.5 No, they will not produce an interference pattern. They are not coherent sources.

Q35.6 The location of points of constructive and destructive interference depend only on the wavelength of the wave and the distance between the two sources so the positions of the nodal and antinodal lines would be unaffected. There would be total reinforcement at points on the antinodal curves but there would not be total cancelation at points on the nodal curves.

Q35.7 In principle, yes. But the wavelengths of gamma rays is 10^{-10} m or less. The two slits, or coherent sources, would have to be about 10^{-10} m apart. This is about the size of atoms and would be very difficult to achieve.

Q35.8 Red light has a wavelength of about 700 nm. For two slits separated by $d =$ 25 cm, $\lambda / d = 3\times10^{-6}$. The angular positions of adjacent maxima and minima would be very close together and the pattern of light and dark fringes would not be observable.

Q35.9 The first dark fringe on one side of the central bright fringe is located at $\sin\theta = \lambda / 2d$. If this fringe is at $\theta = 90^\circ$ it isn't observed. This gives $d = \lambda / 2$. If $d < \lambda / 2$ the central bright fringe is spread over the entire screen and no dark fringes are observed.

Q35.10 The phase angle ϕ does indeed have these values at points on the screen where there is totally constructive interference. But at all other points on the screen ϕ has values differing from these.

Q35.11 Yes, there would be overlapping interference patterns, for each wavelength of the light. The pattern would have a rainbow appearance. There would be bright fringes of each color but no dark fringes because at each point on the screen there will be constructive interference for some wavelength.

Q35.12 No, amplitudes must be added. For electromagnetic waves, for example, it is the electric and magnetic fields that obey the principle of superposition. Intensities are always positive and don't interfere.

Q35.13 The water can act as a non-reflecting coating, as described in Example 35.7.

Q35.14 For a soap film with air on either side of the film, there is a half-cycle phase shift when light is reflected off the top of the film but no phase shift due to reflection when it reflects off the bottom surface. The net phase difference due to the reflections is a half-cycle phase difference. So when the film is very thin and there is no additional phase difference introduced by the path difference, the light reflected from the top and bottom of the film interferes destructively. For a soap film on glass rays reflected at both the top and bottom surfaces of the film have a half-cycle shift upon reflection so there is no net phase difference due to the reflection. Then for a very thin film the two light rays reflected from the top and bottom of the film are in phase and interfere constructively.

Q35.15 For visible light reflecting from a thick film, the values of *m* in Eq.(35.17) will be large and the wavelength change for successive values of *m* will be very small. Closely spaced wavelengths will have constructive interference and no one wavelength appears to be emphasized more than any other in the reflected light. The interference still occurs but its effects are unobservable. A film might be considered thick if it is more than 10λ thick.

Q35.16 Conservation of energy requires that light of a given wavelength either be reflected or transmitted. The reflected and transmitted intensities must add up to the incident intensity. So, if the light isn't reflected due to interference then it must be transmitted.

Q35.17 If the intensity of the reflected light is small then the intensity of the light transmitted through the film is large. See Q35.16.

Q35.18 At a very thin part of the film the path difference due to the thickness of the film introduces negligible phase difference. To get destructive interference then there must be a net half-cycle phase difference due to the reflections. When light in air reflects from the top surface of the oil film there is a half-cycle phase shift since $n_{\text{oil}} > n_{\text{air}}$. So there must be no phase shift when the light traveling in oil reflects off the interface between oil and water at the bottom surface of the film. This will be the case if and only if $n_{\text{oil}} > n_{\text{water}}$.

CHAPTER 36
DIFFRACTION

Discussion Questions

Q36.1 To observe diffraction effects the size of the aperture must be similar to the wavelength. The wavelengths of sound waves and water waves range from a few centimeters to several meters and we commonly experience apertures of this range of sizes. But visible light has a wavelength on the order of 10^{-7} m and apertures of this size don't occur for objects that we normally experience. It is the short wavelength, not the high speed, that makes diffraction effects for light less common.

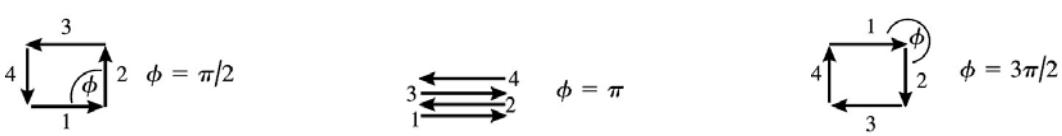
Q36.2 Fresnel and Fraunhofer diffraction are based on the same physical process, it is just their mathematical description that is different. The Fraunhofer diffraction regime allows for simplifying approximations.

Q36.3 $\theta = 1.22\lambda / D$ is the smallest angular separation that can be resolved. Small θ corresponds to larger resolving power. (a) Smaller D increases θ and decreases the resolving power. (b) Larger f means smaller λ and this decreases θ and increases the resolving power. (c) Larger λ means larger θ and decreases the resolving power.

Q36.4 From Eq.(36.3) we find the width of the central maximum to be $\Delta y = 2x\lambda / a$. (a) Decreasing a increases the width of the central maximum. (b) Decreasing f increases λ and this increases the width of the central maximum. (c) Decreasing λ does decrease the width of the central maximum. (d) Decreasing x does decrease the width of the central maximum.

Q36.5 The first dark fringe on one side of the central maximum is at an angle θ given by $\sin\theta = \lambda / a$. This fringe doesn't appear on the screen if $\lambda / a > 1$ so $a = \lambda$ is the maximum slit width for which no dark fringe is seen.

Q36.6 The phasor diagrams are similar to those in Figure 36.14 in the textbook. An interference minimum occurs when the phasors add to zero. (a) The phasor diagram is given in Figure DQ36.6a. There is destructive interference between the light through slits 1 and 3 and between 2 and 4. (b) The phasor diagram is given in Figure DQ36.6b. There is destructive interference between light through slits 1 and 2 and between 3 and 4. (c) The phasor diagram is given in Figure DQ36.6c. There is destructive interference between light through slits 1 and 3 and between 2 and 4. Note that maxima occur when $\phi = 0, 2\pi, 4\pi$ etc. Our analysis shows that there are three minima between the maxima at $\phi = 0$ and $\phi = 2\pi$. This agrees with the general result that for N slits there are $N-1$ minima between each pair of principal maxima.



(a) (b) (c)

Figure DQ36.6

Q36.7 For eight slits the phasor diagrams must have eight vectors. At a minimum the phasors for all slits sum to zero. The diagrams for $\phi = 3\pi / 4$ and for $\phi = 5\pi / 4$ are sketched in Figure DQ36.7a and the diagrams for $\phi = 3\pi / 2$ and for $\phi = 7\pi / 4$ are sketched in Figure DQ36.7b. For $\phi = 3\pi / 4$, $\phi = 5\pi / 4$ and $\phi = 7\pi / 4$ totally destructive interference occurs between slits four apart. For $\phi = 3\pi / 2$, totally destructive interference occurs with every second slit.

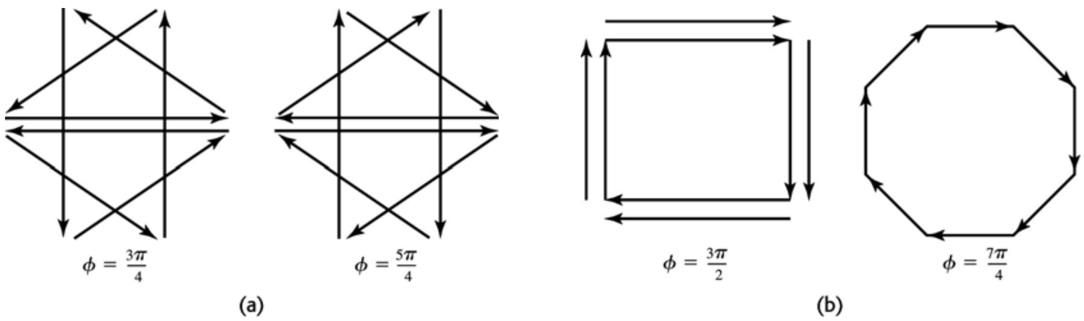


Figure DQ36.7

Q36.8 The raindrop acts as an aperture. If the drop is small enough the central diffraction pattern for each wavelength is as wide as the angular spread of the rainbow. This will happen when the drop size is on the order of the wavelength of the visible light.

Q36.9 The narrow horizontal width increases the horizontal spread of the sound in the central diffraction maximum. If the audience is distributed horizontally but not vertically it is not desirable to have a wide diffraction maximum in the vertical direction, so the vertical dimension of the speaker is somewhat larger than the wavelength of the sound. If the audience is also spread in the vertical direction the speaker would need also to be narrow in the vertical direction to spread the sound in this direction, so should be more nearly square.

Q36.10 High frequency sounds have smaller wavelength. The small speaker diameter makes λ / a larger so the central diffraction maximum for the high frequency sound waves is spread over a wider angular range.

Q36.11 In this application we want the central diffraction maximum for light from the pits to be narrow. This requires a small λ / a. Narrow pits (small a) means more information stored in the disk, but a small a requires a small λ to keep λ / a and the width of the diffraction maximum small.

Q36.12 The minimum angular separation of objects that can be resolved is $\theta = 1.22\lambda / D$. Resolving finer detail means smaller θ and this happens for smaller λ. The Hubble can see finer detail in the ultraviolet.

Q36.13 (a) For a minimum to occur, the sum of all phase differences between the slits must add to zero, so the phasor diagram closes on itself and the sum of all the phasors is zero. This requires that $N\phi = 2\pi m$, for some integer m. Therefore, $\phi = m\left(\frac{2\pi}{N}\right)$. But when $\frac{m}{N} = n$, where n is an integer, $\phi = 2\pi n$. In this case all the phasors are in phase and their magnitudes add to give a principal maximum. (b) There are $N - 1$ values of m that satisfy $\phi = m\left(\frac{2\pi}{N}\right)$ between the value nN and $(n+1)N$, where n is an integer.

Q36.14 In x-ray diffraction with a crystal the slit spacing d is the separation between atomic planes in the crystal. A typical value of d in this application is 0.1 nm (Example 36.5). The wavelength of visible light is about 500 nm, so $\lambda / d = 5000$ and no interference fringes can be seen, only the central bright fringe.

Q36.15 With a grating the bright fringes are much narrower. The centers of the fringes can be measured more accurately and there is less overlap of fringes from different wavelength than with two slits.

Q36.16 The phase difference for the radio signal received by the different antennas produces an interference pattern when the signal from all antennas is combined coherently. The sharp interference fringes allow for accurate determination of the wavelengths in the signal, just as a diffraction grating can be used to measure the wavelengths in a sample of visible light.

Q36.17 The image will be distorted when 500-nm light is used for viewing. In Fig.36.29b the different wavelength will produce a maximum in the diffracted wave at a point different from P'. The centers of successive bright fringes on the developed film will differ by integer wavelengths at different points.

Q36.18 The maxima in the diffracted wave will occur at different points for each wavelength in the white light and no image will be seen.

Q36.19 Bright and dark areas of the image will be opposite what they are in the object. That is, where the object is bright the image will be dark.

CHAPTER 37
RELATIVITY

Discussion Questions

Q37.1 (a) The proper time is measured in a frame in which the two events occur at the same place. That is the frame of reference of the moving train; the passenger on the train measures the proper time. (b) The proper length of an object is measured in a frame in which the object is at rest. The proper length of the train car is measured in the frame of the moving train; the passenger on the train measures the proper length. (c) The proper length of the sign is measured in a frame attached to the ground; you measure the proper length of the sign.

Q37.2 No. The effect cannot occur before the cause. In order for event A to cause event B some sort of signal must travel from event A to event B and this signal cannot travel faster than the speed of light. Therefore, if two events are causally related their separation in space and their separation in time in any frame must be such that a light signal can be passed between them. Events that satisfy this constraint occur in the same order in all reference frames. If event A occurs before event B in some frame and B before A in other frames then the space and time intervals between the events in any frame must be such that a light signal cannot be passed between them; they cannot be causally related.

Q37.3 (a) With respect to the astronaut riding with the rocket the light travels the same distance to each wall and the events are simultaneous. (b) Relative to the person at rest on earth, the walls of the rocket move to the right as the light travels to them so the light travels a shorter distance to reach the rear wall and this person observes *B* occurring first.

Q37.4 In the rest frame of the spacecraft the passenger sees her distance from the asteroid increase as the asteroid moves away from her at $0.9c$. Simultaneously, she sees her distance from the earth decrease as the earth moves toward her at $0.9c$. The passenger receives the radio messages simultaneously when her distance from the asteroid is equal to her distance from earth. Therefore, she deduces that the signal from earth was sent at a time when she was farther from earth than she was from the asteroid. Since the signal from the earth must travel a greater distance than the signal from the asteroid, the passenger deduces that the signal from the earth must have been sent before the signal from the asteroid.

Q37.5 No. By a distance of 70 light years we mean a distance between two points measured in the frame of the earth. The separation between these two points is shortened relative to an observer moving very close to the speed of light and such a traveler can travel between the two points in a time, measured in his frame, that is less than 70 years.

Q37.6 You would need to travel at high speed in the direction along the major axis of the ellipse. (See Problem 37.45.)

Q37.7 In the thought experiment of Section 37.2 the two events occur at different places in each frame. If the two events are simultaneous in a frame and occur at the same point in that frame then they are simultaneous in all frames. The effect described in Section 37.2 arises from the differences in travel time of a light signal from each event to the observer.

Q37.8 Larry measures the proper length l_0 of the train car. Adam measures the length *l*, where $l = l_0\sqrt{1-u^2/c^2}$ and *u* is the speed of the train relative to the earth. The length *l* is less than l_0. Since David is moving in the same direction as the train, the speed of the train relative to him is smaller than the train's speed relative to Adam. Therefore, the length contraction is a bit less for David than for Adam, but the difference is very small since the bicycle moves much, much slower than the train. All three observers measure different lengths for the train car. The length measured by Larry is the greatest and the length measured by Adam is the smallest.

Q37.9 No. Eq.(37.27) shows that p increases without bound as v approaches c. Similarly, Eq.(37.38) shows that E increases without bound as v approaches c.

Q37.10 She is correct. As soon as a massless particle, such as a photon, is created, it has speed c. Photons never have speed less than c. Recent experimental evidence suggests that perhaps neutrinos do have mass.

Q37.11 No. Einstein's second postulate is about the speed of light in vacuum.

Q37.12 No. The speed of light is the same for all observers. Both the wavelength and frequency are altered by the motion of the source but they still satisfy $c = f\lambda$. When λ is shortened f is increased and the speed of light is unaffected by the motion of the source.

Q37.13 In principle an increase in energy corresponds to an increase in mass. But the amount of mass associated with ordinary amounts of thermal energy is quite small. For example, $E = mc^2$ says that an energy of 900 J corresponds to a mass of 1×10^{-14} kg. So, in practice this is not a measurable effect.

Q37.14 Common experience involves speeds where Newtonian mechanics applies to high accuracy. Experiments that show a breakdown of Newtonian mechanics are technologically advanced and could only be performed starting in the 20th century. Also, relativistic mechanics is conceptually more complicated and is built on the foundation of Newtonian mechanics. Conceptually, it would have been difficult for scientists to develop relativistic mechanics if they didn't first have a deep understanding of Newtonian mechanics.

Q37.15 The effects of special relativity would be commonplace.

CHAPTER 38
PHOTONS: LIGHT WAVES BEHAVING AS PARTICLES

Discussion Questions

Q38.1 They are similar in that they have energy and momentum. Photons are different in that they have zero rest mass and travel at the speed of light. Photons have neither mass nor charge. The speed of photons depends on the material in which they travel but within any given material they always have the same speed and can't be accelerated.

Q38.2 The energy the electron receives from the light would be $2hf$ rather than hf. $2hf$ would replace hf in Eq.(38.4). The threshold frequency f_0 would be $f_0 = eV_0/(2h)$, half what it is when only one photon is absorbed.

Q38.3 The number of photons emitted each second by ordinary light sources is very, very large. (See, for example Exercise 38.3.) There is no noticeable time interval between arrival of photons.

Q38.4 We would expect that the photon (particle) nature of light would be more important at the high-frequency end of the electromagnetic spectrum. High-frequency photons each have more energy and momentum so the quantized photon nature of light would be more apparent at high frequency.

Q38.5 A photon with wavelength 400 nm, at the short-wavelength edge of the visible spectrum, has an energy of 3.1 eV. Table 38.1 shows that the work function for most common metals is larger than this. And, surface impurities, such as oxide layers, increases the work function considerably. And any electrons lost from the surface are quickly replaced from the surrounding air. Photoelectric effect experiments must be done with very clean surfaces in high vacuum.

Q38.6 A certain threshold energy is needed to alter a molecule of the emulsion of the film such that the spot is "exposed". Therefore, there is a threshold frequency below which a photon doesn't have enough energy to expose the film. Longer wavelength light has lower frequency. The threshold need not be sharp; the lower the energy of the photon the less efficiently it can expose the film.

Q38.7 Yes. The higher frequency ultraviolet photons individually have enough energy to damage molecules in the skin.

Q38.8 Only electrons initially at the surface of the metal leave the surface with kinetic energy $hf - \phi$. For electrons that start within the metal some of the energy delivered by the photons is used to bring the electron to the surface of the metal, so less energy is left as kinetic energy of the released electron. More photoelectrons come from within the metal than from its surface; the photons usually penetrate beneath the surface of the metal before they are absorbed.

Q38.9 Above the threshold frequency the number of photoelectrons is independent of the frequency of the light. One photon absorbed produces one photoelectron. Changing the frequency changes the energy of each photon but doesn't change the number of photons.

Q38.10 A photoelectron receives energy from a single photon and the energy of a photon depends on its frequency or wavelength. Therefore, the maximum speed and kinetic energy of a photoelectron depends on the frequency of the light and is independent of the intensity of the light. And there is no time delay. The only statement that is true is (a).

Q38.11 No. A molecule of the phosphor that converts ultraviolet radiation to visible light absorbs an ultraviolet photon and emits only part of the energy as a photon, so the emitted photon has less energy and larger wavelength than the absorbed photon. The molecule can't emit a photon of more energy than the energy of the photon that was absorbed.

Q38.12 $K_{\max} = hf - \phi$. (a) No. Light of greater intensity produces more photoelectrons but doesn't change their maximum kinetic energy. (b) Yes. Increasing f increases $K_{\max}$. (c) No. Increasing λ decreases f and decreases $K_{\max}$. (d) No. Increasing ϕ decreases $K_{\max}$.

Q38.13 The photon transfers some of its energy to the electron so the scattered photon has less energy than the incident photon. This means that $f' < f$. Eq.(38.10) shows that the energy $P_{\mathbf{e}}^2 / 2m$ transferred to the electron depends on the angle ϕ. But for all values of ϕ the electron gains energy and the photon loses energy and $f' < f$. The only exception to this is $\phi = 0$; for this ϕ no energy is transferred to the electron and $f' = f$.

Q38.14 Yes, photons can scatter from protons and Eq.(38.7) still applies. But now m is the proton mass rather than the electron mass. The shift in wavelength will be much less.

Q38.15 Energetic electrons that have been accelerated through high voltages can produce x rays when they are stopped in solid pieces of metal.

Q38.16 Photons travel in straight lines in the direction of propagation of the light. What is oscillating in an electromagnetic wave are electric and magnetic fields. Photons have no charge and therefore an oscillating electric or magnetic field wouldn't exert a force on a photon to cause it to move along with the oscillation of the fields.

Q38.17 No. To get a wave function for the light that is localized in space a spread of frequencies (or wavelengths) must be combined. If the wave packet is spread out in space, as in a steady, continuous beam, it can be of more precise wavelength.

CHAPTER 39
PARTICLES BEHAVING AS WAVES

Discussion Questions

Q39.1 $\lambda = h/mv$. The electron has a smaller mass so has a larger λ.

Q39.2 $\lambda = h/p$. $K = p^2/2m$, so $p = \sqrt{2mK}$. $\lambda = h/\sqrt{2mK}$. The electron has a smaller mass so has a larger λ.

Q39.3 For a photon $\lambda = h/p$. This is identical to Eq.(38.5) that relates the momentum of a photon to the wavelength of the light. The de Broglie wavelength of the photon and the wavelength of the associated electromagnetic wave are the same.

Q39.4 The electron remains a point particle. When the electron goes through the hole its position in the direction parallel to the hole is determined to within the diameter of the hole and by the uncertainty principle this introduces an uncertainty in the component of its momentum in the direction that is parallel to the hole. This uncertainty in transverse momentum causes a spread in the location where the electrons strike the screen.

Q39.5 To emit light in the $n = 2$ to $n = 1$ transition there needs to be atoms in the $n = 2$ excited state. Galaxies contain a lot of atoms in the $n = 2$ excited state so must have a high temperature. The intergalactic medium must have few atoms in the $n = 2$ excited state so must be cold.

Q39.6 In the equations in Section 39.3 that describe the hydrogen atom replace e^2 by Ze^2 to get the corresponding equations for a one-electron ion with atomic number Z. Eq.(39.14) shows that E_n for hydrogen is proportional to e^4, so the corresponding E_n for Li^{++} are larger by a factor of 9. Eq.(39.8) shows that r_n for hydrogen is proportional to $1/e^2$ so the corresponding r_n for $\text{Li}^{+}+$ are smaller by a factor of 1/3.

Q39.7 A photon with energy E has momentum $p = E/c$. If the atom has mass M and gains momentum $p = E/c$ when the photon is emitted, the recoil kinetic energy is $K_\text{r} = p^2/2M = E^2/2Mc^2 = (E/2Mc^2)E$. Mc^2 is the total rest mass energy of the atom. E is the transition energy for the atom and is much, much less than the rest mass energy of the atom. Mc^2 for a proton is 938 MeV and E is typically less than 10 eV, so $E/2Mc^2$ is very small. The recoil kinetic energy is a very small fraction of the photon energy and is negligible in Eq.(39.5).

Q39.8 It can be done, and has been done, in the Franck-Hertz experiment. This is described in Section 39.3.

Q39.9 For a gas of atoms the electrons in each atom are in discrete energy levels. For a solid there are electrons in bands of energies and the electrons can have any of the energies within these bands and there is a continuous spread of transition energies. See Section 42.4.

Q39.10 The intensity versus wavelength of the emitted light follows the Planck radiation law. This law (Fig.39.32 and Eq.39.24) and also the Wien displacement law (Eq.39.21) show that the spectral emittance $I(\lambda)$ peaks at smaller wavelengths as the temperature of the object increases. This causes a shift in color. The underlying reason for the shift in $I(\lambda)$ is that at higher temperatures higher energy levels of the electrons in the solid are populated so emission can occur from these higher levels. Transitions from higher energy levels have greater transition energies and the emitted photons have higher energies and shorter wavelengths. Eq.(39.19) also shows that the total intensity of the emitted radiation increases as T^4.

Q39.11 If we apply Bohr's angular momentum quantization to a planet, the quantum numbers n are huge and orbits for successive n are infinitesimal close in radius. No discrete nature of the orbit radius of the planet is observable.

Q39.12 The de Broglie wavelength of an electron with kinetic energy 54 eV is $\lambda = h/p = h/\sqrt{2mE} = 1.7\times10^{-10}$ m. The wave nature of the electrons is of no consequence in this application.

Q39.13 Extremely short wavelength electromagnetic waves have very energetic photons that would damage the object being examined.

Q39.14 $E_n = -(13.6\text{ eV})/n^2$ so an electron in a higher n shell has more energy. $v = (2.19\times10^6\text{ m/s})/n$. An electron in a higher n shell also has a smaller speed in its orbit and therefore less kinetic energy. But the electron with larger n has more (less negative) potential energy and this gives it more total energy. In fact, $U_n = -2K_n$, so $E_n = -K_n$ and smaller K_n means greater E_n since E_n is negative.

Q39.15 No. For Δy on the order of the diameter of the bullet, Δp_y from the uncertainty principle is exceedingly small and produces no observable effects.

Q39.16 If one slit is covered a single-slit diffraction pattern is obtained, not a two-slit pattern. Both slits must be open for each electron so in this sense all electrons go through both slits. If we want to show the wave nature of electrons by observing an interference pattern in a two-slit experiment, we cannot at the same time show their particle nature by requiring the electrons to go through one slit or the other.

Q39.17 Eq.(39.30) says that the energy cannot be precisely measured in a very short time. Energy conservation can be violated only for very short times.

Q39.18 Eq.(39.30) says that the longer an atom is in an excited state, the more precise is the energy of that state and therefore the smaller the spread in transition energy when the atom makes a transition from the excited state to the ground state. The energy of the emitted photon equals the transition energy, so photons emitted in a transition from a long-lived atomic state have a narrower spread in energy and wavelength. For ordinary light sources the atoms are in the excited states for very short time intervals and the energy uncertainty of those states is large.

Q39.19 Yes, a grating of any number of slits could be used. The diffraction pattern would be the same as for light whose wavelength is the same as the de Broglie wavelength of the electrons; the electrons would strike the screen only within narrow lines on the screen. The uncertainty principle would not be violated. The greater the number of slits the more uncertain is the position of the electron when it passes through the grating so the more precise can be its direction of travel.

Q39.20 The aluminum foil is a polycrystalline material. It consists of randomly oriented microscopic crystals. For a single crystal a pattern like that shown in Fig.36.20 would be observed. The location of the dots depends on the orientation of the crystal relative to the electron beam. The pattern from the polycrystalline foil includes contributions from crystals of all orientations so each dot is replaced by a continuous ring of dots.

Q39.21 The resolution is determined by λ/a, where a is the lens diameter. The de Broglie wavelength of the electrons is orders of magnitude smaller than the wavelength of visible light. So the electron microscope is better able to resolve small objects. The magnification of a microscope is (approximately) $M = (25\text{ cm})s_1'/f_1 f_2$ (Eq.34.24). To have a large magnification M the focal lengths f_1 and f_2 of objective and eyepiece must be very small. It is difficult to make extremely small focal length lenses for visible light. It is much easier to make small focal length electrostatic lenses for electrons.

Q39.22 When you measure the temperature of an object by inserting a thermometer into it you change the temperature of the object at least slightly because some heat is transferred between the object and the thermometer. If you measure the current in a circuit with an ammeter you add the ammeter resistance in series and alter the current you are trying to measure.

CHAPTER 40
QUANTUM MECHANICS

Discussion Questions

Q40.1 For these macroscopic objects the de Broglie wavelength is exceedingly small and the fact that it is not quite zero is of no consequence. Such objects exhibit no wave properties.

Q40.2 The analogy is sensible.

Q40.3 It is the quantity $\left|\Psi(x,t)\right|^2$ that describes the position of the particle and $\left|\Psi(x,t)\right|^2 = \left|\psi(x)\right|^2$ is real even though $\Psi(x,t)$ has complex values.

Q40.4 For a one-dimensional system $\left|\psi(x)\right|^2 dx$ is the probability that the particle will be found in the region x to $x+dx$. The particle must be somewhere, so $\int_{-\infty}^{\infty}\left|\psi(x)\right|^2 dx$ must be unity. But $\int_{-\infty}^{\infty}\left|\psi(x)\right|^2 dx = 1$ is just the normalization condition. $\psi(x)$ must be normalized if $\left|\psi(x)\right|^2 dx$ is to be the probability of the particle being found between x and $x+dx$.

Q40.5 No, it just means that the position probability distribution function $|\Psi|^2$ at each point in space doesn't vary in time. Yes, states of constant energy are stationary states.

Q40.6 $n=0$ given $k=0$ and from Eq.(40.29), $\psi(x)=0$. This wave function is a trivial solution to Eq.(40.25) that corresponds to no particle being present. $\psi_n = -\psi_{-n}$ and wave functions differing by a constant describe the same physical state; $|\psi_n|^2 = |\psi_{-n}|^2$ so negative n values don't correspond to additional solutions.

Q40.7 The area under a graph of $|\psi|^2$ versus x between x_1 and x_2 is the probability that a value between x_1 and x_2 will be found if the position of the particle is measured. The total area under $|\psi|^2$ would be unity; there is unit probability that the particle will be somewhere.

Q40.8 The classical particle travels between the walls with constant speed so it is equally probable that it will be found at any x. The graph of the probability distribution as a function of x would be a horizontal line for $0 \le x \le L$ and would be zero for $x<0$ or $x>L$. For $|\psi_n|^2$ with $\psi_n(x)$ given by Eq.(40.35) the oscillations become very rapid as n increases and $\int_x^{x+\Delta x} |\psi_n|^2 dx$ is the same for all intervals Δx. So, yes, the probability distributions approach the classical result as n becomes very large.

Q40.9 Yes, Eq.(40.26) is the form of two traveling waves propagating in opposite directions. The stationary states can be thought of as a standing wave produced by superposition of wave functions for particles traveling in opposite directions due to reflections at the walls of the box.

Q40.10 The wave functions for all states are symmetric about $x = L/2$ (the center of the box) so the particle is equally likely to be found in either half of the box. The probability of finding the particle in the right half of the box is 1/2, for any level.

Q40.11 The probability of measuring the position of the particle and getting one of these values of x is zero. The velocity of the particle is not zero at these points.

Q40.12 $E_n = n^2\pi^2\hbar^2 / 2mL^2 = p_n^2 / 2m = h^2 / 2m\lambda_n^2$. States of definite E have definite λ and definite momentum p. But measurements of $\vec{p}$ yields $p\hat{\boldsymbol{i}}$ and $-p\hat{\boldsymbol{i}}$ with equal probability so the states of definite energy aren't states of definite momentum vector.

Q40.13 States of definite energy are not states of definite wavelength and are not states of definite momentum. $p = h/\lambda$ so if p doesn't have a definite value then λ doesn't have a definite value. For $0 < x < L$, the wave function is a combination of functions $\sin kx$ and $\cos kx$ that have definite $k = p/\hbar$. But for $x < 0$ and $x > L$ the wave function is of a different form and isn't characterized by this same k.

Q40.14 $|\psi|^2 = 0$ at the walls so there is zero probability that a measurement of the particle's position yields the values 0 or L. But the presence of the walls affects the wave function and energy levels of the particle. If the walls are removed, these quantities change. In this sense the particle strikes the walls.

Q40.15 As Fig.40.14 shows, the wave function extends into the region outside the well and there is some probability for the particle to be found there. From the normalization condition $\int_{-\infty}^{\infty} |\psi(x)|^2\, dx = 1$ and $\int_0^L |\psi(x)|^2\, dx$ will be less than 1.

Q40.16 Since the wave function extends out into the classically forbidden region ($x < 0$ and $x > L$) for the finite well but not for the infinite well (box), the wavelength in a given energy state of the finite well is larger than the wavelength in the corresponding level of the infinite well. $E_n = h^2 / 2m\lambda_n^2$ inside the box, so larger λ means lower energy.

Q40.17 Yes, $E_1 \to 0$ as $U_0 \to 0$. As $E_1 \to 0$ the wave function extends farther and farther into the $x < 0$ and $x > L$ regions. As the momentum approaches zero its uncertainty becomes small, the localization of the particle in x becomes less, in accordance with the Heisenberg Uncertainty Principle.

Q40.18 The rate of the exponential decay of the wave function with distance outside the well depends on $\kappa = \sqrt{2m(U_0 - E)} / \hbar$. κ becomes small as $E \to U_0$. The particle can tunnel farther into the potential barrier when its energy is close to the top of the barrier.

Q40.19 Yes, it is a contradiction. In classical Newtonian mechanics the particle cannot be in this region but in quantum mechanics there is some probability of the particle being there.

Q40.20 The electron density is spherically symmetric so the potential energy function must be spherically symmetric. And the potential energy corresponds to a potential well.

Q40.21 You would expect that for a given particle energy the probability of tunneling would decrease as the barrier height is increased. As the barrier height is increased, $E - U_0$ becomes more negative and in classical mechanics it is more strongly forbidden for the particle to be in the barrier.

Q40.22 No. A measurement of the position of the particle gives a definite result. The wave function means that there is some probability that the whole particle can be found in the region $x < 0$ and some probability that the whole particle can be found in the region $x > L$.

Q40.23 No. Oscillations in $|\psi(x)|^2$ continue to be present. They just get more and more rapid as n

increases.

Q40.24 The wave function is smaller in the region $-A/2 < x < A/2$ than in the region $-A < x < A/2$ plus $A/2 < x < A$. So, even though these two regions are the same size, there is greater probability of finding the particle in the outer half ($-A < x < A/2$ plus $A/2 < x < A$) than in the center half ($-A/2 < x < A/2$). The particle is more likely to be found near the turning points at $x = \pm A$ than around $x = 0$. This corresponds to the classical result that $v = 0$ at $x = \pm A$ and that v is a maximum at $x = 0$. The particle spends more time near the turning points.

Q40.25 Harmonic oscillator: $E = \left(n + \frac{1}{2}\right)\hbar\omega$. Levels are equally spaced. $n = 0$ for the ground state. $n = 2$ for the second excited level.
Particle in a box: $E = n^2\pi^2\hbar^2 / 2mL^2$. Level spacing increases with increasing *n*. $n = 1$ for the ground state and $n = 3$ for the second excited level.
Hydrogen atom: $E_n = -me^2 / 8\varepsilon_0 n^2 h^2$. Level spacing decreases with increasing *n*. $n = 1$ for the ground state and $n = 3$ for the second excited level.

Q40.26 In either case the wave function is zero at the infinite wall at $x = 0$ and is zero for $x < 0$. For $E_1 < U_0$ the particle is in a bound level and the wave function exponentially decreases for $x > A$ and is zero for $x \geq B$. The wave function in the region $0 < x < A$ is the wave function for a free particle and will have zero nodes for the ground state and more if it corresponds to an excited state. For E_3 the wave function is zero for $x \leq 0$ and for $x \geq B$. For $0 < x < B$ the wave function is that of a free particle and the wave number k is larger in the region $0 < x < A$ than in the region $A < x < B$. Sketches of the possible wave function for each energy are shown in Fig.DQ40.26.

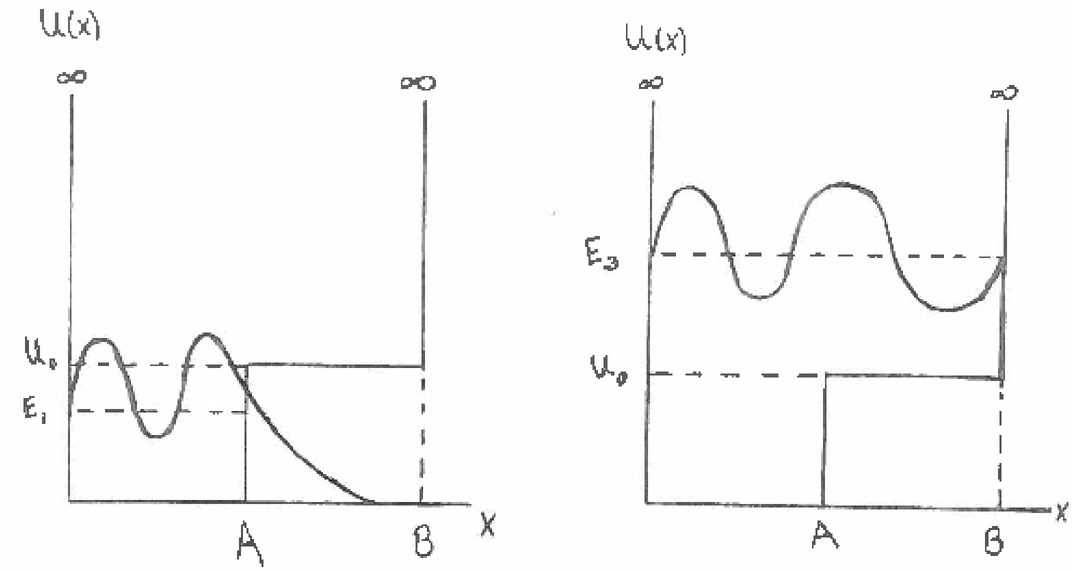

Figure DQ40.26

Q40.27 If the wave function is $\Psi(x,t) = \psi_2(x)e^{-iE_2t/\hbar}$, a measurement of the energy yields the value $E_2 = \dfrac{4\pi^2\hbar^2}{2mL^2}$. If the wave function is $\Psi(x,t) = \dfrac{1}{\sqrt{2}}\left(\psi_1(x)e^{-iE_1t/\hbar} + \psi_2(x)e^{-iE_2t/\hbar}\right)$, a measurement of the energy can yield either $E_1 = \dfrac{\pi^2\hbar^2}{2mL^2}$ or $E_2 = \dfrac{4\pi^2\hbar^2}{2mL^2}$. There is equal probability of each result so the average result for many measurements with an ensemble of identical particles would be

$E_{\text{av}} = (E_1 + E_2)/2 = \dfrac{5}{2}\left(\dfrac{\pi^2\hbar^2}{2mL^2}\right)$. No, we can't say that before the measurement each particle has energy E_{av}. Before the measurement each particle has equal probability of having energy E_1 or E_2.

CHAPTER 41
ATOMIC STRUCTURE

Discussion Questions

Q41.1 The probability is given by $|\psi^2|dV$, where ψ is the wave function. $|e^{i\phi}|=1$ so the two wave functions give the same probability.

Q41.2 The Bohr model and the Schrodinger analysis yield the same expression for the energy levels (Eq.(41.21)). The Bohr model says the angular momentum of an electron in energy state *n* is $L=n\hbar$. The Schrodinger analysis says $L=\sqrt{l(l+1)}\hbar$, where $l=0,\ 1,\ \ldots,\ n-1$. Therefore the two approaches give quite different results for the angular momentum. The Schrodinger analysis says $L_z=m_l\hbar$, with $m_l=0,\ \pm 1,\ \pm 2,\ \ldots,\ \pm l$, so L_z is quantized and the possible orientations of $\vec{L}$ are restricted (Fig.41.6). In the Bohr model the electron travels in an orbit of definite radius whereas in the Schrodinger analysis the location of the electron is determined by a position probability distribution (Fig.41.8).

Q41.3 Yes, in principle. But the spacing between allowed orbits is exceedingly small and the quantization of the orbits is not observable. (See Discussion Question 39.11.)

Q41.4 The electrons exert forces on each other so their motions are correlated.

Q41.5 For ionized atoms the magnetic force on the net charge would overwhelm the force due to the spin magnetic moment.

Q41.6 (a) Yes, $L=\sqrt{l(l+1)}\hbar$, with $l=0,\ 1,\ \ldots,\ n-1$. Except for $n=1$ there are two or more *l* values for each *n*. For example, for $n=2$ the value of *l* can be 1 or 0. (b) Yes. A given value of *l* can correspond to any value of *n*, for $n=l+1,\ l+2,\ l+3,\ \ldots$. For example, $l=1$ can have $n=2,\ 3,\ 4,\ \ldots$.

Q41.7 A homogeneous field exerts zero net force on a current loop (Section 27.7).

Q41.8 The Pauli exclusion principle requires that no two electrons have the same set of quantum numbers. They have the same n, l, and m_l, so they must have different m_s values.

Q41.9 Eq.(27.27) says that the interaction energy is minimum when a dipole is in a direction parallel to the field direction and a maximum when the dipole direction is opposite to the field. The $m_s=+\frac{1}{2}$ state has $S_z=+\hbar/2$ and by Eq.(41.38) its spin magnetic moment is in the $-z$-direction. So for this state $\vec{\boldsymbol{\mu}}$ and $\vec{\boldsymbol{B}}$ are antiparallel and the interaction energy between the spin magnetic moment and the field is a maximum. The $m_s=-\frac{1}{2}$ state has $S_z=-\hbar/2$ and its spin magnetic moment is in the $+z$-direction. For this state $\vec{\boldsymbol{\mu}}$ and $\vec{\boldsymbol{B}}$ are parallel and the interaction energy is a minimum. The $m_s=-\frac{1}{2}$ state has lower energy.

Q41.10 In an alkali metal there is a single electron outside filled shells. The electron density in the filled shells is at a smaller radius than for the electron outside the filled shells. This reduces the correlation of the motion of the outermost electron with that of the rest of the electrons. For the transition metals there are two or more electrons outside of filled shells. These electrons occupy similar regions of space and their motion is highly correlated.

Q41.11 The $4s$ level lies below the $3d$ level. Lower levels fill first in building up the ground states of atoms.

Q41.12 Example 21.1 showed that the electrical force between two alpha particles is immensely larger than the gravitational force between them. The same holds true for an electron and a nucleus; the gravitational force is totally insignificant in atomic structure.

Q41.13 They all have a $1s^2 2s^2 2p^6 3s^2 3p^6$ core plus some number of $4s$ and $3d$ electrons. The chemical properties do not depend much on how many $4s$ and $3d$ electrons there are in the atom.

Q41.14 Zinc ($Z = 30$) has filled subshells through $4s^2 3d^{10}$. The next lower energy orbital is the $4p$ so the neutral gallium atom has a $4p$ electron outside a zinc configuration core. Ga^+ has the same electron configuration as zinc. Ga^- has a $4p^2$ configuration outside a zinc configuration core.

Q41.15 For example, without spin helium would have an electron configuration of $1s2s$ and would not be chemically inert. The periodic table indicates double filling of each n, l, and m_l sublevel and this requires a fourth quantum number since the Pauli exclusion principle doesn't allow two electrons with the same set of quantum numbers.

Q41.16 The orbital motion of the electrons results in a magnetic field that is internal to the atom.

Q41.17 In the alkali atoms there is one electron outside filled shells. The electron density in the filled shells is at smaller radius than the outer electron so the electrons in the filled shells are effective in screening the nuclear charge. The outer electron sees an effective nuclear charge of close to $Z_{\text{eff}} = 1$. In a noble gas there are several electrons in the same shell and therefore in the same region of space. These electrons only partially screen the nuclear charge from each other and Z_{eff} is larger than 1.

Q41.18 The ionization potential is $-E_n$, where E_n is the level energy of the least tightly bound electron. The level energy is given by Eq.(41.45) and depends on the n quantum number for the level and the effective nuclear charge Z_{eff} seen by the electron. Z_{eff} is less than Z because of partial screening of the nucleus by the other electrons in the atom. As electrons are removed, for the outermost electron the screening of the nucleus by the other electrons decreases. For a given n the ionization potential decreases when Z_{eff} decreases. The ground state electron configuration of magnesium is $1s^2 2s^2 2p^6 3s^2$. For a $3s$ electron the other electrons screen the nucleus and Z_{eff} is approximately unity. For Mg^+ the ground state electron configuration is $1s^2 2s^2 2p^6 3s$ and 10 inner electrons screen the nucleus from the 3d electron and Z_{eff} is approximately 2. For Mg^{2+} the ground state electron configuration is $1s^2 2s^2 2p^6$. The screening for an outermost electron is further reduced. And now it is a $n = 2$ rather than a $n = 3$ electron that will be removed in ionization and this further increases the ionization potential.

Q41.19 The effect on an electron of all the other electrons is approximated in an average way by a spherically symmetric potential energy function. In reality the interaction between any pair of electrons depends on the instantaneous location of the two electrons and the electron motions are correlated. The central field approximation is a simplified treatment of the electron-electron interaction.

Q41.20 There is little screening for a $1s$ electron in gold except for the screening from the other $1s$ electron so the $1s$ electron has $Z_{\text{eff}} \approx 78$. Eq.(41.45) says the energies scale by Z_{eff}^2. So the energy for gold is about $(78)^2 = 6084$ times larger than the energy for hydrogen. It takes 13.6 eV to remove the $1s$ electron from hydrogen. A photon with $E = 13.6$ eV has wavelength $\lambda = hc/E = 91$ nm. The photon is in the ultraviolet. It takes about $(78)^2$ (13.6 eV) = 8.3×10^4 eV to remove a $1s$ electron from gold. A photon with $E = 8.3\times10^4$ eV has wavelength $\lambda = hc/E =$ (91 nm)/(78^2) = 0.015 nm. This photon is a hard x ray.

Q41.21 (a) $L^2 = l(l+1)\hbar^2$. $L_z^2 = m_l^2\hbar^2$. The maximum value of m_l is l so the maximum L_z^2 is given by $\left(L_z^2\right)^2_{\max} = l^2\hbar^2$. $L^2 - \left(L_z^2\right)^2_{\max} = l\hbar^2$. $L = L_z$ only when $l = 0$. For $l \neq 0$, $L > (L_z)_{\max}$. (b) A classical object can have $L = L_z$ even when L is not zero, if $\vec{L}$ is in the z-direction.

Q41.22 No. At the absorption edge the transition of the electron in the atom is from the $1s$ level to the lowest unfilled bound sublevel of the atom. All electrons in the atom are still bound. However, when the hole in the $1s$ orbital is filled by an outer-shell electron, the energy released can either result in the emission of an x ray or in the ionization of one of the electrons.

Q41.23 No. Hydrogen cannot emit photons of energy greater than 13.6 eV. A photon with this energy has wavelength $\lambda = hc/E = 91$ nm. This photon is in the ultraviolet and does not have enough energy to be an x ray.

Q41.24 For either electron the possible results of a measurement of S_z are $+\frac{1}{2}\hbar$ or $-\frac{1}{2}\hbar$. For either electron the probability of each result is $\frac{1}{2}$. If measurement of S_z for electron 1 yields the value $+\frac{1}{2}\hbar$, then the wavefunction collapses to $\psi(\vec{r}_1,\vec{r}_2) = \psi_\alpha(\vec{r}_1)\psi_\beta(\vec{r}_2)$ and a measurement of S_z for electron 2 gives a result $-\frac{1}{2}\hbar$ with unit probability.

Q41.25 For either electron a measurement of S_z yields the value $+\frac{1}{2}\hbar$ with unit probability. If measurement of S_z for electron 1 yields the value of $+\frac{1}{2}\hbar$ then a measurement of S_z for electron 2 yields a value of $+\frac{1}{2}\hbar$ with unit probability.

CHAPTER 42
MOLECULES AND CONDENSED MATTER

Discussion Questions

Q42.1 The hydrogen bond is unique to hydrogen-containing compounds because only hydrogen has a singly ionized state with no remaining electron cloud. The hydrogen ion is a bare proton and is much smaller than any singly ionized atom. It is small enough to get between two atoms, polarizing them and attracting them by means of the induced dipoles.

Q42.2 Part of the bonding is due to electrons transferred from one atom to the other and part is due to the sharing of electrons between the atoms.

Q42.3 H_2^+ can't form a pair of positive and negative ions so the bonding must be covalent.

Q42.4 The molecule stretches when it is in a higher rotational level and I increases when r increases. So, the $l = 19 \to l = 18$ transition corresponds to a larger moment of inertia.

Q42.5 Near the bottom of the potential well the potential energy curve (Fig.42.1) of a diatomic molecule is parabolic and therefore the same as for a harmonic oscillator. But higher in the well, the well is wider than a parabola. The wider well corresponds to lower energy levels so adjacent levels move closer together as n increases.

Q42.6 For the vibrational levels the force constant is the same but the reduced mass m_r is double for D_2 so the vibrational frequency ω is smaller by a factor of $1/\sqrt{2}$. The vibrational energies for D_2 are smaller by a factor of $1/\sqrt{2}$. The equilibrium separation r_0 is nearly the same for H_2 and D_2. But m_r is double for D_2 so I is double. The rotational energy is proportional to $1/I$ so the rotational levels for D_2 are smaller by a factor of 1/2.

Q42.7 The temperature of the molecules is very low so there is very little electronic excitation and very, very few electronic energy transitions, and these are the transitions that emit visible light. The only excited levels of the molecules that are populated are low-lying rotational levels. The transition energies between these levels and the ground state are small and the photons emitted correspond to radio waves.

Q42.8 The typical level structure is shown in Fig.42.8. The spacing between the $n = 0$ and $n = 1$ vibrational levels is much larger than the spacing between the lowest few rotational levels.

Q42.9 For the lowest vibrational energy levels the energies are the same as for a harmonic oscillator. But the potential energy function $U(r)$ differs from that for an ideal spring for r farther away from the equilibrium separation. And if the molecule gains enough energy the molecule can dissociate into two atoms; the "spring" can break.

Q42.10 The outer electron charge clouds of adjacent atoms overlap significantly. Because of the electrical interactions between the electrons and because of the exclusion principle, the wave functions and energy levels are altered from their atomic values. The valence electron wave functions become less localized and extend over several atoms.

Q42.11 A conductor has a partially filled conduction band. An insulator has an empty conduction band and a large energy gap between the empty conduction band and the filled valence band. (See Fig.42.19.)

Q42.12 Ionic crystals have energy levels similar to those of isolated ions and absorb only certain discrete wavelengths of visible light. For metals the electrons in the partially filled conduction ban can absorb visible light of any wavelength and undergo a transition to an unfilled level in the band.

Q42.13 The molecules move as free particles and their kinetic energy is given by $\frac{3}{2}kT$. The energy of electrons in the conduction band of a metal depends on the Fermi energy of the band. Fig.42.23 shows that the distribution of electron states within the conduction band depends weakly on temperature.

Q42.14 In a semiconductor there is a small energy gap between the empty conduction band and the filled valence band. Increased pressure or temperature can promote electrons into the conduction band and gives the material metallic properties.

Q42.15 The energy levels of solid zinc are different from those of the isolated atom. The strong interaction of the atoms in the solid and the exclusion principle distort the wave functions of the electrons. The electron energies shift and form energy bands. (See Fig.42.18.)

Q42.16 A typical electron moves so rapidly within the metal that the effect of the ions and other electrons is a uniform potential energy function. The electron-electron interactions are effectively screened due to the high density of electrons. The net charge of the ion cores and valence electrons is smoothly distributed throughout the volume of the solid and gives rise to a constant potential everywhere except at the surfaces of the solid.

Q42.17 The nonlocalized electrons in the conduction band are free to move around and conduct both electricity and heat. The wires that conduct electricity also tend to conduct heat from the hot device.

Q42.18 Donor atoms need to have a loosely bound valence electron outside of an electron configuration similar to that of silicon or germanium. This loosely bound electron doesn't participate in the covalent bonding when these atoms are added to silicon or germanium. An acceptor atom needs one additional electron to reach an electron configuration like that of silicon or germanium. The acceptor atom needs one more electron in order to form the same number of covalent bonds as silicon or germanium when added to those materials.

Q42.19 Yes. Just add electrons to the surface, to fill the holes.

Q42.20 Yes. This is explained by Fig.42.24. At low temperatures there are no electrons in the conduction band. At high temperatures a large number of electrons have enough energy to be in the conduction band.

Q42.21 This is discussed in Section 25.2. As the temperature increases, the ions of the conductor vibrate with greater amplitude, making it more likely that a moving electron will collide with an ion. This impedes the drift of electrons through the conductor and reduces the currents. For a semiconductor, at increased temperatures electrons can gain energy from the thermal motion and move into the conduction band.

Q42.22 Add twice as many acceptor impurity atoms as donor impurity atoms.

Q42.23 The saturation current I_S is the maximum current from n to p when a reverse bias voltage is applied. This current is due to free electrons in the p region moving into the n region. An increase in temperature increases the number of free electrons in the p region.

Q42.24 If the device is too small there isn't enough space between the source and drain to prevent electrons from tunneling through and producing a drain current even when there is no gate potential.

The device will leak current when the gate is turned off and there is not supposed to be any current.

CHAPTER 43
NUCLEAR PHYSICS

Discussion Questions

Q43.1 The electric charge of the protons causes the transition energy for a spin flip to depend on the chemical environment of the protons. The purpose of the proton MRI is to study that environment. Neutrons have no charge so their spin flip energy is insensitive to their chemical environment.

Q43.2 The second term represents the decreased binding of nucleons on the surface of the nucleus whereas the first term represents binding of nucleons in the interior of the nucleus. The surface area of a sphere is $4\pi R^2$ whereas the volume is $\frac{4}{3}\pi R^3$. Therefore, as the nucleus becomes larger a smaller fraction of the nucleons are on the surface.

Q43.3 When nucleons are combined to form a nucleus some of their mass is converted into the binding energy of the nucleus.

Q43.4 When $Z > N$ there is too much Coulomb repulsion between pairs of protons for the nucleus to be stable.

Q43.5 The magic numbers for which there are known elements are 2, 8, 20, 28, 50 and 82. The elements with these values of *Z* are helium, oxygen, calcium, nickel, tin and lead. The nuclei of these elements are unusually stable.

Q43.6 No. As the number of electrons increases so does the nuclear charge Ze and the binding energy of each of the innermost electrons increases roughly as Z^2. The binding energy per electron for uranium is much larger than it is for hydrogen.

Q43.7 Radioactive decay must be energetically allowed. Proton or neutron decay normally isn't energetically allowed.

Q43.8 The interior of a star undergoing helium fusion is much hotter than the interior of a younger star that is undergoing hydrogen fusion. The Coulomb repulsion of helium nuclei ($Z = 2$) is four times that of hydrogen ($Z = 1$) for the same separation and much higher temperatures are needed to give the helium nuclei sufficient kinetic energy to overcome the Coulomb repulsion and get close enough to fuse.

Q43.9 ${}^{214}\mathrm{Pb}$ is an unstable isotope of lead. Other isotopes of lead are stable (${}^{206}\mathrm{Pb}$, ${}^{207}\mathrm{Pb}$, and ${}^{208}\mathrm{Pb}$).

Q43.10 The nuclei with the shorter lifetimes are less abundant.

Q43.11 α particles are much more massive. A β particle with the same energy has a much greater speed.

Q43.12 (a) Nucleon number unchanged, atomic number increases by 1 so this is β^- decay. (b) Nucleon number decreases by 4 and atomic number decreases by 2 so this is α decay. (c) Nucleon number unchanged and atomic number decreases by 1 so this is β^+ decay.

Q43.13 An electron has charge $-e$ and has nucleon number zero. A positron has nucleon number zero and charge $+e$ so it can be represented as ${}^{0}_{+1}\beta$. A neutrino has nucleon number zero and no charge so can be represented as ${}_{0}^{0}\nu$. An antineutrino has nucleon number zero and no charge so can be represented as ${}_{0}^{0}\overline{\nu}$.

Q43.14 The alpha, beta or gamma decays are associated solely with the nucleus and are unaffected by the electronic structure of the atom. Electron capture however involves capture of an orbital electron and is affected by the chemical binding of the atom since the chemical binding affects the orbital electrons.

Q43.15 The atomic electron that receives the energy has enough energy to break free from the atom; it can get energy greater than its binding energy. If this is an inner electron an x ray photon can be emitted when an outer shell electron in the atom falls into the inner-shell hole.

Q43.16 Human activity has burned carbon containing compounds in coal and oil and released this carbon into the atmosphere as CO_2 .

Q43.17 Biological material that was recently alive has an activity of 0.255 Bq or greater per gram of carbon. Older samples have a much lower activity per gram of carbon because of radioactive decay of the ^{14}C in the sample. Contamination with modern material would give a falsely high activity and cause an underestimation of the age of the sample. Older samples have a smaller activity and the relative effect of contamination is larger.

Q43.18 ^{226}Ra is being continually produced as a decay product from other more long-lived radioactive nuclei. One example is the ^{238}U decay series shown in Fig.43.7.

Q43.19 This is explained by Fig.43.2. When lighter nuclei fuse to form a nucleus lighter than ^{62}Ni the binding energy per nucleon in the product nucleus is greater than in the two original nuclei and energy is released. When a heavy nucleus splits into two pieces, each heavier than ^{62}Ni, the binding energy per nucleon increases and energy is released.

Q43.20 The binding energy per nucleon is greater in the daughter nuclei than in the parent nucleus (see Fig.43.2). Therefore, a large amount of energy is released in the fission and this energy appears as kinetic energy of the daughter nuclei.

CHAPTER 44
PARTICLE PHYSICS AND COSMOLOGY

Discussion Questions

Q44.1 It is possible that parts of the universe contain antimatter. Only if we detect annihilation events from the presence of both matter and antimatter or by detecting particles, such as high energy antiprotons or neutrinos that come to us from these regions could we tell. Light emitted by anti-atoms does not differ in any way from light emitted by normal atoms; there are no antiphotons. If we went there the matter in us and in anything we bring with us would annihilate with the antimatter and be converted into energy.

Q44.2 Yes. Conservation of energy can be violated for short periods of time. Empty space is not really empty. It is filled with these pairs of so-called virtual particles that individually exist for very short periods of time.

Q44.3 They have similar masses and occur with both positive and negative charges. There is a neutral pion but no neutral muon. Muons are leptons and are fundamental though unstable particles. Pions are mesons and are composed of one quark and one antiquark. Muons have spin $\frac{1}{2}$; pions have spin zero.

Q44.4 We live on the surface of a very massive object that because of its mass exerts a large enough force on objects around us to have very noticeable effects on their motion. The electrical force between a pair of fundamental particles that carry charge is much larger than the gravitational force they exert on each other. But electric charge is usually present in equal amounts of positive and negative charge and the electrical forces largely cancel out.

Q44.5 The π^0 is composed of quark-antiquark pairs. The quarks and antiquarks annihilate and their mass is converted entirely into the energy of the photons.

Q44.6 Electron decay into two photons violates conservation of charge and conservation of lepton number. The photons have zero charge and zero for all lepton numbers. Electron decay into two neutrinos also violates conservation of charge and conservation of lepton number. Neutrinos have zero charge and no pair of neutrinos has the same set of lepton numbers as an electron.

Q44.7 They both have spin $\frac{1}{2}$. Some of each are charged and some of each aren't. All baryons have mass. In the standard model the neutrino leptons have zero mass. The lightest baryons are heavier than the electron. Leptons are fundamental. Baryons are composite particles, composed of three quarks. Leptons have lepton numbers and baryons have baryon number and both these are separately conserved.

Q44.8 Both leptons and quarks are fundamental particles. Both have spin $\frac{1}{2}$. Leptons have integer Q/e; quarks have fractional Q/e. Leptons and quarks have different conserved quantities (lepton number for leptons and baryon number, strangeness, charm, bottomness and topness for quarks).

Q44.9 To obtain the quark content of an antiparticle, replace quarks by antiquarks and antiquarks by quarks in the quark composition of the particle. (a) The antineutron has quark content that consists of three antiquarks, $\bar{u}\bar{d}\bar{d}$. (b) This is different from the quark content of the neutron and the neutron is not its own antiparticle. (c) The antiparticle of the ψ has quark content $\bar{c}c$. This is the same as the quark content of the ψ and the ψ is its own antiparticle.

Q44.10 No. In the standard Big Bang model the universe was once in a small volume. Since then it has expanded and all points are moving away from all other points. There is no stationary center.

Q44.11 See the CAUTION statement in Section 44.6. The universe is thought to be infinite. It has no edges, so there is nothing "outside" of it and it isn't "expanding into" anything. The expansion of the universe simply means that the scale factor of the universe is increasing.

Q44.12 The cosmological principle says that the universe looks essentially the same from all observation points. If the universe had an edge it would look very different to an observer at the edge than it would to someone in the interior, far from the edge.

Q44.13 The cosmological principle requires that the universe look essentially the same from all observation points. H_0 must be constant in space so that in all directions galaxies appear to be receding from any observer anywhere in the universe. It can't be different at different places. But this does not prevent H_0 from changing in time. In fact, the most recent astronomical observations suggest that H_0 is now larger than it was in the past.
